STRICTURE OF THE ŒSOPHAGUS.[1]

BY E. FLETCHER INGALS, A.M., M.D.,

PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMAN'S MEDICAL COLLEGE; PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE, CHICAGO, ILL.

STRICTURE of the œsophagus consists of a narrowing of the tube, resulting usually from simple inflammatory thickening or malignant disease, and characterized by difficulty in deglutition, especially of solids. It is more frequently met with in men than in women, and usually occurs in early life. It is not infrequent among children, and a few congenital cases have been observed. Those strictures resulting from swallowing hot or acrid fluids are usually found at the upper part of the tube, just back of the cricoid cartilage. Next in frequency is the lower portion of the tube, near the cardiac orifice of the stomach. The stricture may be single or multiple. Usually not more than one or two inches of the tube is involved, and the obstruction may be slight, or so great as to almost occlude it. When a stricture has existed for a considerable time, the œsophagus above it is apt to be dilated, as the result of detention of food and fatty degeneration of the muscular walls. If the stricture is very close, the œsophageal walls below it are usually found to be atrophied.

Though the disease is occasionally spontaneous, or results from simple inflammation, or possibly from causes that cannot be ascertained, it is usually of traumatic origin in early life, but generally of a malignant nature when found in those past fifty years of age. Most frequently the stricture results from swallowing hot or acrid fluid accidentally, or with suicidal intent, but there is a considerable number of cases in which neither accident nor symptoms of acute or chronic inflammation can be remembered by the patient. These are said to be of spontaneous origin. It is probable, however, that in most or all of these cases a history of inflammation would be present if the patient's memory were unfailing. Rarely, cases may be of syphilitic or tuberculous origin, and exceptionally, the disease may be rheumatic.

The first symptom of the disease is difficulty in deglutition, which may come on suddenly and last only during a single meal, or may continue for two or three days. Usually, this symptom then disappears for a time, but returns after a few days or weeks. The intervals become shorter and shorter and the attacks longer, until finally the obstruction is constant. The dysphagia is first experienced on attempting to swallow hard or solid boluses, but as the disease progresses it becomes more and more marked, until the patient has to live entirely on liquids, and finally, in extreme cases, even these cannot be swallowed. Frequently spasm is excited on attempts at deglutition, and the food may be at once regurgitated. As the contraction becomes narrower and the œsophagus above it dilates, food may pass part way to the stomach, and remain there for several hours before it is expelled. In such cases the extent of dilatation may be estimated by the amount of food regurgitated. When the disease is of malignant origin, the food expelled is frequently found more or less coated with blood or pus.

In the malignant cases dysphonia and more or less dyspnœa are usually present, at some time during the course of the disease, as a result of pressure on the recurrent laryngeal nerve, and consequent paralysis of the vocal cord. If paralysis of the abductor muscles become sufficient, dangerous, or even fatal, dyspnœa will ensue, unless tracheotomy is performed.

In some instances spasm of the œsophagus is a frequent symptom, the patient being at times unable to swallow anything, whereas, at other times, he can swallow without much difficulty. Pain is often experienced on deglutition of solid masses, especially where the disease is of a malignant character. A sense of pressure on the lungs is sometimes complained of, emaciation occurs, and owing to insufficient supply of nourishment the patient becomes weak and nervous, and is easily exhausted.

Diagnosis.—A thorough examination with the laryngoscope may enable the physician to exclude diseases of the pharynx, or to discover paralysis of the vocal cords. By auscultation during deglutition of fluids, a gurgling sound may be frequently detected over the stricture, due to the passage of bubbles of air.

Stricture of the œsophagus may be distinguished from tuberculous laryngitis by the constitutional symptoms, by the pulmonary symptoms and signs, and by inspection of the larynx. The pain during deglutition is much greater in tuberculous laryngitis than in stricture of the œsophagus, excepting perhaps when the latter is of a cancerous nature.

Tumors of the larynx or pharynx, and some of those of the œsophagus, may be readily detected by laryngoscopic examination. Other tumors of the œsophagus may usually be detected by the passage of the œsophageal bougies.

Spasmodic stricture of the œsophagus frequently causes quite as much difficulty in swallowing, at least for a time, as in organic disease. The symptoms are not so very different from those of the latter, but in the former a large-sized œsophageal bougie may be readily passed into the stomach. The difficulty in deglutition in the spasmodic affection comes on suddenly, lasts for a short time, and then entirely disappears, to recur again possibly after weeks or months; whereas the symptoms of the organic disease steadily increase in severity without cessation, though they are subject to exacerbations.

The existence of a stricture may often be suspected or determined by consideration of the history; and this impression may possibly be verified by inspection or palpation with the finger, or by auscultation over the œsophagus while the patient swallows fluid. But the most exact method of diagnosis consists of passing bougies or probes into the œsophagus. This should be done in all cases before making a diagnosis, excepting when there is reason to fear ulceration or great weakening of the œsophageal walls, as in some cases of malignant disease. In making this exploration, the instrument should, if possible, be carried carefully through the contracted portion and into the stomach, in order to determine whether more than one stricture exists. By the size of the instrument which can be passed, we ascertain the calibre of the stricture, and by the amount of resistance we can form some estimate of the nature of the tissues causing the obstruction. Great care should be used in the examination, especially when there is fear of malignant disease, or when there may possibly be ulceration of the œsophagus; otherwise the tube may be torn, and a dangerous accident result. The instruments recommended for the purpose are ordinary soft catheters or bougies, graduated œsophageal dilators of the same material as the flexible English ca-

[1] Read before the Illinois State Medical Society, May 8, 1890.

theter, olivary bougies attached to a whalebone stem, and instruments consisting of a combination of soft with hard rubber. I generally employ in children the ordinary soft bougie with a tapering, bulbous point, and for adults a long whalebone stem to which is attached an ivory olivary body. These olives should be conical at both extremities, otherwise it has happened that an instrument that has been passed through the stricture could not be removed without great difficulty. The surgeon should be careful that the olive is firmly fastened to the stem.

Prognosis.—Non-malignant strictures sometimes progress very slowly, and the patient may live for years before succumbing to the marasmus which will finally result from a deficient supply of food. Malignant strictures are fatal usually in from eight to eighteen months. Cases resulting from burns, scalds, or the ingestion of acids are generally incurable, and necessitate an unfavorable prognosis, because of the tendency to dilatation of the œsophagus above the stricture, and finally ulceration, abscess, or gangrene. The prognosis is comparatively favorable in most cases where the stricture is not very narrow, and has resulted from catarrhal inflammation or indeterminate causes. If, however, the condition has been neglected for a long time, so that the hypertrophied muscles have undergone fatty degeneration, and the tube has become dilated, the prognosis will be much less favorable, though, occasionally, patients live for many years, even with large pouches from the walls of the œsophagus. In fatal cases death may result from an abscess caused by a pressure of food above the stricture, or from pulmonary or other diseases, or from gangrene, resulting from the reduced condition of the system.

In spasmodic stricture the prognosis is favorable if proper treatment is adopted, but, as will be illustrated by cases to be reported, the patient may be reduced to an alarming condition if this is neglected, and I have no doubt that some die for want of surgical interference.

Treatment.—In the treatment of this disease, nourishment that can be easily swallowed must be provided for the patient, and during exacerbations, or when the stricture is very close, nutritive enemata must be employed. Whenever obstruction to deglutition exists, the œsophagus should be carefully examined, and if found to contain a foreign body it must be removed, or, if this is impossible, it should be forced into the stomach. Abscesses pressing on the tube should be evacuated if possible; or, if a tumor is found, its removal should be attempted by forceps, snare, or œsophagotomy.

The iodides are valuable when the disease results from rheumatic or specific inflammation, but in any other case they do little if any good. In malignant cases, arsenic is recommended for its supposed specific effects, and opium must be given in sufficient quantities to relieve pain. In all other cases, and occasionally in the malignant, the most important treatment consists of mechanical dilatation of the stricture. This may be done by interrupted dilatation with bougies of varying size; by internal œsophagotomy and subsequent dilatation; or by electrolysis. External œsophagotomy and subsequent dilatation has also been practised with success in some cases. Internal œsophagotomy is usually considered a hazardous operation, because of the danger of hemorrhage or perforation of the œsophagus. However, this has been successful in a few cases.

Dr. J. O. Roe, of Rochester, has reported three cases successfully treated in this way, nevertheless the method is not in favor with surgeons. External œsophagotomy is indicated in extremely rare cases only, in which the stricture occupies the portion of the œsophagus which can be easily reached, and usually only in those cases in which a foreign body must be removed by an external incision. In the malignant cases external œsophagotomy or gastrotomy have been recommended when there is some special reason for prolonging life a few days, but the average duration of life is only one month in cases which recover after such operation for cancer.

Electrolysis has also been considered a dangerous procedure on account of the proximity of the pneumogastric nerve. However, recent reports of a number of successful cases will stimulate further experimentation in this direction.

The safest method of treatment, and one that has the sanction of age, is by gradual, interrupted dilatation. For this purpose I use soft bougies with tapering and bulbous tips, varying in diameter from 7 to 10 mm., or ivory olivary bodies, conical at both extremities, which may be screwed firmly to a whalebone handle. I have of these a series of eleven, varying in diameter from 8 to 22 mm. Dr. Roe, of Rochester, has invented an œsophageal dilator with a conical tip of soft rubber, which is continuous with a hard rubber base, this being attached to a whalebone stem. This would seem to be an excellent instrument, especially in cases of tortuous strictures where it is sometimes very difficult to pass the olivary bougie. Dilatation has also been practised by passing a thin rubber tube into the stricture and then inflating the tube with air, water, or mercury. Caustics have also been recommended for destruction of the cicatricial tissue, but great care is necessary in their use, and upon the whole they are of doubtful utility. The cure of a case by dilatation often requires a long course of treatment, of from six to eighteen months, but when the difficulty in swallowing solids has only existed a few months or a year, the dilatation may sometimes be completed within a month.

In performing this operation a medium-sized bougie should first be selected to locate the stricture, then smaller ones should be tried until one is found that can be easily passed. The next size larger should then be passed, and this followed by a still larger one, if it does not give the patient too much pain. After three or four days the operation should be repeated, beginning with the next to the largest passed at the last sitting, and following it with the next two larger. This treatment is to be continued at regular intervals until the opening in the œsophagus is sufficiently large, excepting that if inflammation arise, so that the treatment causes considerable pain, the dilatation should be suspended for a few days. Having obtained a sufficient dilatation, the patient must be taught to pass the bougie himself, and should be instructed to introduce it at least once a week for a number of months, and once in two weeks for several months longer. To introduce the bougie, the patient should be seated in a firm chair and given to hold a basin partly filled with water, ostensibly that he may be ready in case of vomiting, but really to prevent him from throwing up his hand to catch the instrument or the arm of the surgeon. Then the bougie having been oiled, the forefinger of the left hand is passed well over the back of the tongue, and with it the bougie is guided into the œsophagus. The instrument will usually pass much more easily at one side of the throat, and will seldom go down the median line. Very little force must be employed in introducing the instrument, never more than two or three pounds pressure being made. The bulb, having been passed slowly through the stricture, should be drawn back into it again and allowed to remain there as long as the patient will tolerate it, which will be for only a few seconds.

Internal œsophagotomy is practised in essentially the same way as internal urethrotomy.

Renewed interest in the electrolytic treatment of strictures of the œsophagus has been excited by the report made by Dr. A. Fort, of Paris, of 19 cases treated by this method; 8 of these were of fibrous character, and after a treatment varying from nine to thirty days, 7 of them have been cured so that bougies from 18 to 20 millimetres in diameter could be readily passed and food of all kinds could be easily taken. The remaining eleven were of a malignant nature and of course were not cured, though they had been much benefited by the treatment and life considerably prolonged. The method, as employed by Dr. Fort, consists in the introduction of a bougie carrying a platinum electrode, which is attached to the negative

pole of the battery, the positive pole being applied over the epigastric region. Through this a current of from fifteen to thirty milliampères is passed, and the electrode is left in position as long as the patient can bear it, which varies from thirty to one hundred and fifty seconds. After removing the electrode, an œsophageal bougie is introduced, one or two millimetres larger than the one that could be originally passed. This treatment is repeated at three or four sittings, it being thought best to proceed slowly in order to avoid accident. Thus far, no hemorrhage or lesion of the walls of the œsophagus has occurred, and the results have been so satisfactory that the method will doubtless be tried by many other surgeons. A brief report on this method is found in the *Journal of Laryngology and Rhinology* for March, 1890.

In my records I find the histories of 26 cases of this disease which I have seen in private practice. I have also seen a considerable number at the dispensary. From these I have selected to report a few that illustrate various interesting points in the history or treatment of this disease.

Case I. *Malignant Stricture.*—M. A——, aged fifty-nine. The patient gave a history of gradually increasing difficulty in swallowing, which had begun sixteen months previously. For five months he had been unable to attend to his ordinary duties. He complained of some pain about two inches to the right of the sternum, upon the level with the second rib. There was an anxious expression of the countenance, and he had emaciated until his weight had been reduced from one hundred and seventy five to one hundred and twenty-three pounds. His tongue was clean, he had a good appetite, but was unable to swallow solid food. There was no hereditary history of malignant disease. The heart and lungs were normal. On attempting to pass an œsophageal bougie, I found the stricture three inches below the opening of the œsophagus, through which I could not pass even the smallest olivary body, which measures eight millimetres in diameter. Diagnosis, malignant stricture of the œsophagus. As a forlorn hope the patient was given iodide of potassium. However, the treatment proved of no avail. He lived about twelve months afterward, making the duration of the cancer in this particular case twenty-eight or twenty-nine months, which was fully a year longer than usual.

Case II. *Malignant Stricture.*—Mrs. P. F——, aged fifty-one, was sent to me by Dr. Best, of Arlington Heights, Ill. She has been troubled with difficulty in swallowing for two years. For the last five months she had found it impossible to swallow any solids, and had suffered severe pain even on attempts to swallow fluids, portions of which often regurgitated through the nose. The doctor informed me that since her trouble with swallowing began, she had suffered from an abscess of the larynx, which had opened externally. For many months there had been some cough and hoarseness. She had been subject to asthma ten years, but had never presented any symptoms or signs of tuberculosis. Her mother was subject to asthma, but there was no other history of hereditary disease. The patient was weak and emaciated, and had a temperature of 100° F. Pulse full, 88 per minute. She said her appetite was good, though she was unable to swallow. Upon examination of the chest I found no evidence of pulmonary disease. Upon examining the larynx I found it congested, the arytenoids somewhat swollen and their posterior surfaces ulcerated, but there was none of the appearance so commonly found in laryngeal tuberculosis. Owing to the evident nature of the disease, I made no attempt to pass an œsophageal bougie, and could only recommend palliative treatment. I suggested for this purpose the application, once or twice daily, of a pigment containing four grains of morphia, thirty grains each of tannic acid and carbolic acid, four drachms of glycerine, and enough water to make one ounce. This pigment I have often used with benefit in tubercular laryngitis, and I have sometimes found that it gives great relief in cancerous affections. This case illustrates the close resemblance which this disease sometimes bears to tuberculosis.

Case III. *Stricture with Dilatation of the Œsophagus.*—P. D. G——, aged thirty-seven. This patient came to me from New Mexico, complaining of having had difficulty in swallowing for the last ten months. He was still able to swallow solids if he used great care. Usually the food lodged when part way down the œsophagus. He had lost fifteen pounds of flesh in the last four months. Although the patient readily answered all questions, careful inquiry could not discover any history of syphilis, therefore I think he had never been infected. No cause for the trouble could be discovered. In attempting to pass a bougie it became caught in a dilated pouch about three inches below the orifice of the œsophagus, and I was unable to get it farther. A No. 17 American catheter passed through the stricture. The patient was given ten-grain doses of iodide of potassium, but was unable to take it; the dose was reduced to five grains, and he was given also one twenty-fourth of a grain of chloride of gold and soda three times a day. I saw him only three or four times, and at the last visit found his power of swallowing had been considerably improved.

Case IV. *Stricture and Polypus.*—H. E——, male, aged eighty-two, came to me from a neighboring State. He had been troubled with difficulty in swallowing for several years. He told me that two or three years before he had coughed up a polypus about three-fourths of an inch long by one-half inch in diameter, and that subsequently there had been no trouble in deglutition for some time; but recently the difficulty was gradually returning. He had a hacking cough but no difficulty in respiration, and the general health appeared good, for one of his age. I had no difficulty in passing a bougie twelve millimetres in diameter, but could not pass the next size larger.

Diagnosis.—Stricture of the œsophagus near the upper portion. No treatment was adopted, owing to the patient's inability to remain in town.

Case V. *Spasmodic Stricture of the Œsophagus.*—B. C. H——, male, aged thirty-two, came to me from Central Wisconsin. He had complained for four months of a raw sensation in his throat, and, for a year, of soreness when eating at the cardiac orifice of the stomach. During this time he had been unable to swallow solids of any kind. He stated that much of his food passed down almost to the stomach, where it lodged and remained for some time, and was then gradually regurgitated, but that whenever any passed into the stomach it caused pain in the region of the lower end of the œsophagus. The patient was weak and anæmic, and had lost nearly sixty pounds of flesh. Pulse normal, temperature 99⅗° F. Appetite and digestion good. There was no evidence of pulmonary trouble, and there was no history of hereditary disease. I found spasmodic contraction of the œsophagus at the cardiac orifice of the stomach, but had no difficulty in passing the largest-sized bougie, 22 mm. in diameter. I thus demonstrated to the patient that he was able to swallow solids of any kind, and by the dilatation relieved the tendency to spasm. I gave him Allen's extract of cannabis indica, one-fourth grain, brucia, one-sixteenth grain, and dextro quinia, two grains, to be taken one-half hour before each meal, and ordered fifteen grains of bromide of potassium to be taken four times daily in water. He returned to his home, and a few weeks later I heard that he had entirely recovered.

Case VI. *Spasmodic Stricture with Slight Fibrous Stenosis.*—H. W. G——, aged twenty-nine, butcher. The patient informed me that he had difficulty in deglutition for the last two years, and that it had become very annoying of late, so that he had to live mainly upon fluids. He did not complain of any pain, but simply of a distressed feeling when trying to swallow. There was an anxious expression of countenance, and he had lost twenty pounds in weight. The pulse was normal, and the temperature 99° F. His father had died of consumption, but there

was no other evidence of hereditary disease. His tongue was coated, but the appetite was good and the digestion normal. From the history, I concluded that there was a stricture of the œsophagus, but I found no difficulty in introducing a large-sized bougie 20 mm. in diameter. This, however, caused some pain. Upon the next visit I introduced my largest bougie, 22 mm. in diameter. The patient was given dilute phosphoric acid and quinine, and subsequently the bromide of potassium. The difficulty in swallowing was cured by the introduction of the largest bougie.

Case VII. *Spasmodic Stricture with Slight Fibrous Stenosis.*—Mrs. B. C——, a frail little woman, aged thirty-eight, came to me from Minnesota, complaining of having had difficulty in swallowing for six months, and being unable to eat solid food. She said that six months previously she had taken a severe cold, and that a physician had made a very strong application, since which time her throat had always felt badly. She attributed the whole trouble to the application, though doubtless it was the result of the cold. She was weak, emaciated, and anæmic, but had a good appetite and good digestion, though she could not swallow solids. There were no signs of pulmonary disease. The passage of an œsophageal bougie, 15 mm. in diameter, gave her considerable pain, and was followed by two or three drops of blood the first time. I repeated the dilatation two or three times and gave her tincture of iron, in doses of from ten to fifteen minims, three times daily. She was also given small doses of belladonna and nux vomica. Four weeks later she left the city, greatly improved in her general condition and cured of the œsophageal trouble.

Case VIII. *Fibrous Stricture.*—T. V. A——, aged sixty-two. This patient came to me in 1884, having had difficulty in swallowing for ten or twelve years. For the past five years he had found it always necessary to have water at hand to wash down solid food. He knew no cause for the disease, but related that when a boy he was subject to frequent rheumatic attacks, and that late in life he had frequently experienced symptoms of gout. The patient, who was a retired physician, thought the disease might be hereditary, as his brother and one niece seem to have been affected in a similar manner. His father and one or two brothers had suffered from gout, but there was no history of other hereditary disease; the patient had suffered from a severe attack of neuralgia about four months previously, and at that time had lost twenty or twenty-five pounds in weight. But this did not seem to be in any way connected with the stricture. He was obliged to live mainly upon fluid food. Upon attempting to pass the œsophageal bougie, I found a long, tortuous stricture opposite the fourth dorsal vertebra, through which it was impossible to pass my smallest olivary body, though I succeeded in introducing without much difficulty an elastic bougie 6 mm. in diameter. Three days later, I introduced one 7½ mm. in diameter, and nine days later one 10 mm. in diameter. The patient shortly afterward had an attack of gout, and the treatment was not resumed. I have occasionally seen this patient on the street during the last six years, appearing about the same as at the last treatment, and I understand that the difficulty in swallowing has not greatly increased. This case is specially interesting because of the existence of the disease in other members of the family, and because of its long duration and the age of the patient.

Case IX. *Membranous Stricture.*—One of the most curious cases of stricture of the œsophagus which I have ever met, was that of a woman about forty-six years of age, who came to me complaining of having been unable to swallow solids for three or four years; she knew of no cause for the trouble. Upon passing the œsophageal bougie, it came to an obstruction about three inches below the upper part of the larynx, but as I made gentle pressure upon it, something which had the feeling of being a thin membrane suddenly gave way and the bougie passed easily into the stomach. I saw her about a week later, and found that she was completely cured.

Case X. *Fibrous Stricture.*—S. O. W——, aged thirty-nine, sent to me by Dr. Bass, of Pullman, Ill. The patient complained of difficulty in swallowing, particularly of solids, which had annoyed him for a year and a half. It was attended by slight pain, referred to the left side of the trachea. The trouble had come on gradually but had steadily increased, until it gave him great annoyance, and his weight had been reduced from one hundred and forty-five to one hundred and twenty-five pounds. There was no evidence of hereditary disease, or of syphilis, and the patient could assign no cause for the trouble, excepting a severe exposure three or four years previously. I found a stricture at the upper part of the œsophagus, through which I passed with some difficulty a bougie measuring 12 mm. in diameter. I saw the patient on an average of once a week for five weeks, and gradually increased the size of the instruments used, until finally, I could introduce without great difficulty one measuring 19 mm. in diameter; and the patient could swallow solids with but little difficulty. He continued in this condition until I lost sight of him, about a year later.

Case XI. *Fibrous Stricture.*—A. A——, male, aged three years and nine months. This little patient was sent to me by Dr. Wheeler, of Latham, Ill., with a history of having swallowed concentrated lye about two and a half years previously. Since then he had been unable to eat any solid food. During this time he had, on several occasions, attempted to swallow solids, but each attempt had been followed by complete closure of the œsophagus, which had lasted for from two to nine or ten days. During these, so-called, spasms he was unable to swallow liquids. Notwithstanding this, the child was well nourished. I found the stricture three inches below the superior opening of the œsophagus, but I was unable to pass even the smallest bougie. As the child was doing well, I recommended that the parents continue the liquid nourishment, and wait until it was older before an attempt at radical treatment should be made.

Case XII. *Fibrous Stricture.*—D. B——, male, thirty years of age. This patient came to me from Wisconsin with a history of gradually increasing difficulty in deglutition, which had prevented him from swallowing solid food for several months. He could assign no cause for the trouble. Upon examination, I found a stricture, about three inches below the upper portion of the larynx, which would admit only one of the smallest-sized bougies. This stricture I gradually dilated as already described, every three or four days for about four weeks, when the largest-sized bougie could be readily introduced and swallowing was accomplished without difficulty. The patient was then taught to introduce the bougie himself, and was directed to do so at least once a week for several months. He returned to his home and a complete cure was effected.

Case XIII. *Fibrous Stricture.*—Mrs. E. M——, fifty nine years of age, was sent to me by Dr. J. R. Jones, of Emporia, Kan. She stated that six months previously she had suddenly found it impossible to swallow solids, and that ever since that time meat could only be swallowed with great difficulty. When the attack first came on, she had been unable to swallow even fluids for three days, but all food taken into the œsophagus had been shortly after regurgitated. Subsequently she was comparatively well for several weeks, when another attack like the first came on and lasted for five days. She then remained comparatively well until three weeks before consulting me. I found no history of hereditary disease. The patient was weak and emaciated, having lost nearly forty pounds. The skin was pale and sallow, and there was some œdema about the ankles. There was no fever, and the pulse was only ninety per minute. She had never suffered any pain from the disease. The appetite and digestion were good. I found a stricture at the cardiac orifice of the stomach, which would admit a bougie of only 11 mm. of diameter. At her next visit, I introduced first a bougie of 11 mm. in diameter, and then one

of 13 mm. On the following visit the same instrument was used, and on the succeeding visit one of 13 mm. and subsequently one of 16 mm. was passed. She could then swallow very much better, but as she was unable to remain in the city, the subsequent treatment was delegated to her home physician. Have never learned the result.

THE STATUS OF PICHI AS A REMEDY IN GENITO-URINARY DISEASES.

By H. H. RUSBY, M.D.,

PROFESSOR OF BOTANY AND MATERIA MEDICA IN THE COLLEGE OF PHARMACY OF THE CITY OF NEW YORK.

THE history of the earliest trials of a new drug, and of its subsequent growth in popular favor, is no less instructive than interesting, for it is determined by many conditions other than the inherent merits or demerits of the drug itself. It will be shaped by the character of the claims under which the article is first presented as compared with its actual properties; by the degree of naturalness or the amount of artificial stimulus attending its introduction; by the amount of preliminary study of the physicians who experiment with and report upon it, and, above all, by the degree of uniformity in the preparations which supply the basis of judgment during the first few years of its career. Thus, to the thoughtful observer, the history of the drug becomes at the same time an exponent of the medical and pharmaceutical tendencies of the times, and a mirror in which are displayed scientific precision and professional intelligence and skill, or the reverse of these qualities. As a result of the variable nature of these conditions we find the early history of almost every drug presenting an alternating series of successes and failures, of eulogies and condemnations. Thus with the discovery of the valuable properties of cocaine, there appeared an avalanche of recommendations for its use in almost every class of diseases. It seemed for a time as though no application of it were left untried, and, according to the reports of the experimenters, more or less benefit resulted in nearly every case. Others, unbiased, and attempting to verify the reports, were disappointed, and there quickly followed an equally voluminous mass of denial and condemnation, a wave of reverse threatening to almost drive cocaine out of consideration as a therapeutic agent. Later a reaction took place, and so, after various oscillations, the real scope and application of the drug became at length established. Similarly the early reports of the powers of sulfonal were roseate in the extreme; and one who had not been through the same experience many times before, might have inferred that our entire list of hypnotics was to become lost sight of in the merits of this new claimant to favor. It was prompt in action, its sleep was a natural one, not followed by any unpleasant symptoms; it was eminently safe, tasteless, and convenient of administration, and, in short, possessed not a single qualification in which it did not show its superiority to all other agents of its class. But soon we found that it was not prompt in its action, nor always certain; that the sleep which it produced and the results which followed differed greatly in different individuals and in different states of the system; that its solubility was very slight; that it was not so free from disagreeable taste as had been represented; and, above all, that it was highly dangerous, and that numerous fatal accidents had been encountered in its administration. At the present time, therefore, sulfonal is under a heavy cloud, from which we expect soon to see it gradually emerge with the explanation that the principal cause of accidents is to be found in ignorant or careless administration.

In encountering one or another of such adverse conditions, pichi has proven no exception to the general rule; and as I was the first to call the attention of American physicians to the remedy—this being done, I may say, independently and ignorantly of its almost simultaneous introduction into France—I have taken unusual interest in following all the details of its several vicissitudes, and have been greatly gratified with the steady manner in which, on the whole, it has made its way to a permanent and growing field of usefulness. The first notice of it in English, so far as I know, was my paper in the *Therapeutic Gazette* of December 15, 1885, p. 110, entitled "The New Chilian Drug 'Pichi.'" In that paper I presented as its probable range of action, 1. The relief of chronic renal congestion without organic degeneration. 2. Of catarrhal inflammation of any portion of the genito-urinary tract, no reference being had to gonorrhœa. 3. A stimulant to digestion and a hepatic stimulant.

I was careful at the same time to point out that it would probably prove injurious in kidney diseases where there was organic change, and to disclaim any belief in its reputed power to remove calculi. I was also careful to indicate the active portion of the plant, and the strong possibility that other portions would be used, and with disappointing results. My reason for this opinion was the fact that, according to the barbarous customs of the country, the shavings of the wood were commonly used, tumblerful doses of the decoction being swallowed. I appreciated the fact that should any considerable demand for the drug arise, it would be obtained through commission-houses, who would purchase it directly from the natives, they in turn collecting it according to their own customs, and that we should have, as a result, a commercial product prepared almost wholly from the wood, which could not be effective except in great doses, and which being used, as was certain to be the case, in doses proper for the preparation from the active portion of the plant, must necessarily result in disappointment. This opinion, as will be seen farther on, has been unhappily justified to a most unusual degree.

The first physician to experiment extensively with the subject of my sketch was Dr. Hal C. Wyman, of Detroit, who found that it produced complete cures in almost every case of cystitis following surgical operations upon the urethra, rectum, or uterus, at the same time curing, in several cases, a chronic cystitis which had long preceded the acute attack for which treatment was instituted. His favorite prescription was:

℞ Fl. ex. pichi..... ℥ j.
Potass. nitrate..... ʒ j.
Simple elixir..... ℥ iij.
M. S.: Teaspoonful once in two hours.

The next report upon it came from Dr. A. Rodriguez, of Buenos Ayres, who found it especially valuable in inflammation of the bladder caused by the mechanical irritation of calculi. He also found that he had been able in many instances to cause the dislodgement and expulsion of calculi small enough to pass through the urethra. He had in addition found it of marked value in the treatment of jaundice and dyspepsia due to deficient biliary secretion. It is important to note that this gentleman administered from two to three ounces per day of the fluid extract. There is little doubt that the preparation here referred to was of the native drug, consisting largely of wood, as this amount of the fluid extract of the leafy tops would have proven highly injurious to his patients.

The next important notice that we find of the action of pichi is in the report presented by M. Limousin, at a meeting of the Therapeutical Society at Paris, in which he expressed the opinion that the resin contained in the drug possessed the power of dissolving the mucin holding together the parts of the calculus, and thus tending more or less to disintegrate it. This statement was confirmed by M. Dujardin-Beaumetz, who was present.

Dr. H. S. Delamere (MEDICAL RECORD, November 12, 1887) next presented a communication showing its great value in the treatment of cystitis following gonorrhœa.

Dr. A. G. Ward (*Medical Age*, 1887, p. 229) reported on its value in an obstinate case of pruritus vulvæ accompanying vesical irritability.

Dr. J. H. De Wolf, of Baltimore (*Medical Age*, 1887, p. 249), concludes from clinical trial, 1, that pichi is a diuretic; 2, that it is a urinary sedative.

In the *Therapeutic Gazette*, 1888, p. 240, Dr. J. H. Tressel reported painful gastric disorders produced by the use of excessively large doses of the fluid extract of pichi. At the same time he reported benefit from its use in cystitis accompanying renal congestion as the result of a cold.

Dr. Peyton Greene (*Therapeutic Gazette*, 1888, p. 368) reported success in the treatment of chronic cystitis, and in cystitis following childbirth. He also expressed the opinion that its lithontriptic action would seem to consist rather in its action as an antilithic than as a solvent.

Dr. George Chaffee (*Medical Age*, 1888, p. 82) was the first, so far as I know, to report favorably upon its action in the treatment of hæmaturia renalis. In this case the symptom was the result of Bright's disease, and was unusually severe, several times threatening the death of the patient, and relief was in all cases promptly obtained by the administration of pichi. The doctor's opinion was thus expressed: "Although pichi is not recommended in organic diseases of the kidneys, I sincerely believe that since November 10th I have carried this patient along, and stayed the progress of his disease as well, if not better, with pichi than I could with any other remedy with which I am acquainted."

In the *Medical Age*, 1888, p. 313, Dr. Oscar S. Armstrong, reporting upon a number of important cures of chronic cystitis, refers particularly to the reduction of inflammation believed to have been caused by the induction of abortion.

In the *North American Journal of Homœopathy* for 1888, Dr. Knight presents a report on its action from the standpoint of the homœopathist. His method was the administration of two to four drops every two hours, or ten drops four times daily. In these doses he found that it produced the best results in allaying a tendency toward a hypersensitive condition of the bladder and urethra bordering upon a true inflammation. Its diuretic action he found to be slight. He had not yet observed any effects in the treatment of cases showing a lithæmic condition, and concluded that an insufficient time had as yet been allowed.

To these I might add a report, given me verbally by my friend Dr. Laurence Johnson, of New York, who found that it increased the severity of acute gonorrhœa. As a result of his trials of it in various conditions, he believed that its greatest value was in overcoming chronic indigestion.

The above are selected from more than one hundred published reports which I have collated, not as being specially favorable, but merely as indicating special features of the therapeutic action of pichi. In the meantime great numbers of reports were published of cases, of which the above may be considered as types, and almost invariably confirmatory of the favorable conclusions therein reached. Without presenting the details of these reports, I may draw from them the following generalizations:

In the treatment of acute cystitis following surgical operation, childbirth, gonorrhœa, or accompanied by acute congestion of the kidney, relief was prompt and strikingly marked, without any published exception except one. In such cases its action corresponds somewhat to a combination of henbane and buchu.

In the treatment of chronic cystitis relief was customary and a cure frequent, the results being probably as good as can be anticipated in chronic diseases, where a neglect of treatment or of its regularity is the almost invariable rule.

As an antilithic, its use very rarely resulted in disappointment. As a lithontriptic it was the fortune of the remedy to meet with its chief reverses. Although in the original references to this action, the language had been carefully guarded against the possibility of misconstruction, yet such misconstruction actually occurred. At the same time, reports in French literature, which were not so conservative, were freely copied, and many attempts at the expulsion of calculi were made, resulting, of course, ordinarily in failure. Notwithstanding the fact that pichi occurs freely in the urine, and is readily enough detected there by its strong odor, yet it must be in such a dilute condition as to produce but little effect in the dissolution of calculi, and any attempt to increase the amount sufficiently to produce such an effect would be ruinous to the stomach and to the general health of the patient. What might be accomplished by urethral injections of a strong solution is not known. So far as I am aware, no experiments have been made in this direction. The failures, however, have resulted chiefly through an unintelligent method of trial. There is abundant evidence leading to the conviction that small calculi are very frequently dislodged and carried away as a result of free treatment with pichi; and there is a prominent practitioner in Louisville, who has quite a large vial filled with these small calculi, which he claims to have removed by the aid of pichi alone.

I hope to be able, during the summer, to present a report of some original investigations of the power of the resin of pichi to dissolve calculi.

The original statements concerning its effect in chronic Bright's disease now require to be accepted with some modification. Notwithstanding the fact that the amount of albumin is often increased, there are a number of cases in which unquestioned and great benefit has resulted in the treatment of this form of disease by pichi; and it is very possible that later and more scientific investigations will show us in just what class of cases of chronic Bright's disease it can be used with advantage.

In the treatment of hæmaturia, particularly, many fortunate results have been reached. At least half a dozen cases have come to my personal knowledge, where our most distinguished practitioners had failed in their application of the ordinary remedies, and in which complete relief was afforded by the administration of pichi. In one of these cases the patient, himself a prominent physician, had previously returned from treatment in Europe as the result of which all hope had been abandoned.

But little systematic attention also has been given to the effects of this drug upon the liver, and yet there is in the reports sufficient evidence to show that there are rich results in store for some practitioner who will patiently investigate its action in this direction. The treatment of dyspepsia and indigestion by this remedy is also an excellent field for clinical research.

One serious objection to the remedy had frequently been urged, namely, its very disagreeable savor; but this was happily overcome by the use of a solid extract encased in gelatine capsules. Another was its tendency to overset the stomach on continued administration; and this was overcome by pushing it for a few doses, and then ceasing the administration for a short time.

The foregoing portion of this paper relates to the early history of the drug, when, as I well know, the preparations were of the same general character and quality, and before an extensive demand had called forth heavy importations of carelessly collected supplies. The uniformly favorable results which I have indicated are amply sufficient to establish the drug as an exceedingly valuable therapeutic agent. Yet we are forced to face the fact that, after two or three years of almost unequalled success in clinical work, unfavorable reports began to be recorded, general disappointment ensued, and many of those who were at first most favorably impressed with the results which had taken place under their own hands, came to distrust the remedy, and to wonder that its subsequent effects were not uniform with the earlier ones. The cause for this change is so clear to me that I have been induced to communicate it in the form of a warning, not only in relation to the remedy now under consideration, but as a fruitful and general source of disappointment

which can readily be avoided, and the responsibility for which, if it occur, rests with the practitioner himself.

In my first contribution I was sufficiently explicit in indicating that the constituents on which the activity of pichi might depend, resided in the leaves, the young twigs, and, to a less extent, in the bark, being almost wanting in the wood. In accordance with this information only the small and leafy twigs were collected, and for a long time little else was used in the manufacture of the American fluid extract, and with the excellent results already recorded. But the favorable reports elicited created a great demand for the medicine, both here and abroad, and importers placed large orders for crude pichi. Having myself collected the small twigs of the original supplies, I was fully aware of the tediousness of the process, and did not anticipate a like care in the procurement of commercial supplies; but I had not looked for the absolute carelessness which was actually displayed. The entire shrubs, with a base diameter of five inches or more, were cut up and tied into fagots, a foot, more or less, in length, the leaves, twigs, and bark, representing scarcely ten, or in many cases even five, per cent. of the weight, the remainder being billets of wood.

In the accompanying cuts, Fig. 2, represents about the best samples which could be obtained from one of these bales, the active portion representing about one-tenth of the weight, but there were very few fascicles even so good as this. Fig. 1, on the other hand, represents a first-class sample, such as yielded the preparations which furnished the basis of the favorable reports from which this paper is compiled. To obtain such material, there was only one possible method, namely, to maintain one's own collectors in the region of production, for it could not anywhere be purchased. This condition of supply has been

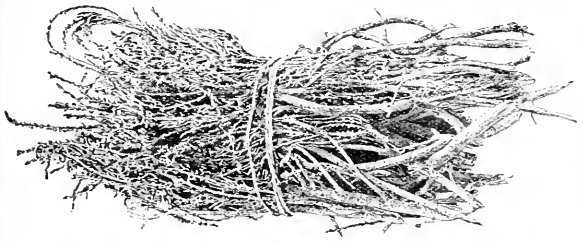

Fig. 1.

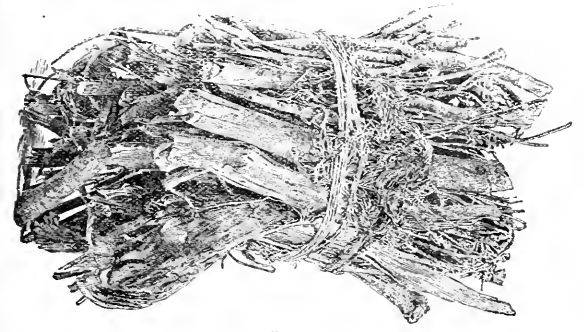

Fig. 2.

in full force up to the present time and still continues. No crude pichi can be purchased either in this country or in Europe, nor even, except through special collections, in its native home, which will not yield a totally distinct preparation from that used in the production of the original favorable results. By far the greater portion of the fluid extract now furnished on prescriptions, possesses a strength only about one-tenth as great as that upon the action of which the accepted dose has been established. How can it be otherwise than that disappointment will follow its use? The fact is sufficiently confirmed by the obviously feeble results communicated by Dr. Knight upon the administration of two to four, instead of fifteen-drop doses, his preparation being, nevertheless, a good one; and such a homœopathic dose is what is being administered by the majority of physicians who prescribe half-drachm doses without assuring themselves that the preparation is from the genuine drug. It is particularly instructive to note, moreover, that in South America, and to a great extent in Europe, where the woody stock is consumed, two and three ounces are given in a day, while here we find as many drachms of a perfect preparation eminently satisfactory. Clearly the occasion of disappointment lies in the carelessness of the prescriber! Many physicians object on principle to specify the preparation upon their prescriptions; but in this class of cases there is no other road to success. Unless the physician satisfies himself that the preparation of pichi dispensed upon his prescription is made from a drug especially collected to order, he need not look for a uniform, and scarcely for a favorable, result. Indeed, it has been a common incident in the history of this drug, that where specifications have continued for a time, and then, through the carelessness born of success, were discontinued, an entirely different product was substituted with an immediately unfavorable result.

PYOKTANIN, THE NEW BACTERICIDE.

By ADOLPH KESSLER, M.D.,

NEW YORK.

Conscious of the fact that this preparation is scarcely known in this country as an antiseptic agent, I consider it my duty to call the attention of the profession to its uses, and to its marvellous efficacy as a pus-destroyer and wound-healer. It is the well-known methylanilin used by microscopists as coloring material in the study and recognition of bacteria, etc., but Professor Stilling, of Strasburg, was the first to employ it as a therapeutic agent in the treatment of ulcers of the cornea, and of other suppurative affections of the eye. Later experiments and observations in Germany proved its great antiseptic virtues in surgical and obstetrical practice, and in syphilitic and cutaneous affections, thus extending its usefulness to the entire domain of the healing art, even to intestinal and other interior ulcerations.

My own personal experience with the remedy is confined to about a dozen cases, but as some of these cases had been under more or less continuous treatment for months, and even years, and had proved utterly intractable under all modes of treatment, and as, moreover, I was rewarded with unexpected and absolutely phenomenal successes by the use of this new remedy, I feel emboldened to express a pretty safe and correct opinion of its value, and the conviction is ripening within me that pyoktanin is the *ideal* antiseptic and pus-destroyer. For, whether we adhere to the theory that suppuration is due to the presence of micro-organisms, or believe with others that it may be entirely independent of bacteria as the result of chemical influences upon the organism, the fact remains that pyoktanin interferes with the causation of suppuration in every form and shape I have thus far met with, sterilizes and aborts the pyogenic matter, and causes rapid improvement, favorable tissue metamorphoses, cicatrization, and healing. Suppurative wounds and old indolent ulcers of long standing show a vast improvement after a few applications of the remedy; chronic purulent discharges cease altogether, and sometimes at once after a thorough exhibition of the antiseptic

over the diseased parts—the microscope even failing to reveal any pus-cells—and intractable ulcerations that have for months and years baffled all treatment with caustic and antiseptic remedies, the highly lauded corrosive sublimate included, assume in a short time conditions most favorable to granulation and cicatrization.

I can, however, better fulfil the object of this paper by briefly referring to two typical cases, which stand out prominently and illustrate in a marked manner the wonderful efficacy of pyoktanin.

A young gentleman with syphilitic ulcerations of the frontal and temporal bones extending to the scalp, with a steady and copious suppuration that had continued for nearly two months without being checked, consulted me on the 13th of this month, as he did not care to follow the advice of his last physician, to go to a hospital and have a radical operation performed. The case looked bad, indeed, but I resolved to try the pyoktanin first before resorting to severer measures. On the 15th, after evacuating and draining off a considerable quantity of clear pus and cleansing the parts, I freely employed a strong solution of the antiseptic all over the ulcerating surfaces, without giving the patient any noticeable pain or inconvenience. This single application produced two surprising effects: A total cessation of suppuration, the scanty discharge being of a purely sanguineous character, and a marked diminution of the pain and tenderness which had heretofore characterized the *locus morbi*. There has been no further appearance of pus since, and under continued daily dressings the patient is making a good recovery, feeling free from pain and vastly improved in health and spirits. As an indorsement of this paper I presented the patient to Dr. Shrady, the able surgeon, and the editor of the MEDICAL RECORD.

A far more important and complicated case is the next one. Mrs. M—— has been partially paralyzed and bedridden for years, totally unable to move about for eighteen months, since which time she has been afflicted with gangrenous dermatitis involving the right foot and leg and part of the left foot, not to speak of decubitus and other painful ailments. All attempts to better the condition of the affected parts had proved futile, and numerous medical attendants had abandoned the hopeless case in utter despair. When I first saw the patient on April 28, 1890, the sad history of the case, as well as the terrible aspect of the affected extremities, filled me with dismay, and I felt at a loss what to do. The whole right foot presented a putrid sloughing mass covered over with a layer of extremely offensive pus, and the slightest movement of either extremity wrung from the patient torments of pain. With the use of aristol and the bituminated iodoform, I obtained a temporary success in improving the condition of the parts and relieving the great suffering, but it proved only a short respite, and the suppuration furthermore continued uninterruptedly.

In this emergency I resorted at last to the use of the pyoktanin, applying it in substance, in form of a large pencil, to every part of the affected extremities, being careful to bring every particle of the sloughing surfaces under the influence of the antiseptic, and the effect of this first application was not only most gratifying, but in every sense miraculous. Within twenty-four hours every trace of a suppuration that had been going on for nearly eighteen months without cessation had disappeared, together with the horribly offensive odor that had accompanied it, and the ulcerating, sloughing tissues were almost magically transformed into a dry, clean, healthy-looking surface, upon which granulations began to form. I repeat this process daily, partly with the solid pencil, partly with a strong solution, and while suppuration, fetor, and extreme painfulness have wholly disappeared, granulation and cicatrization progress favorably, and there is every prospect of such a *restitutio ad integrum* as the constitutional condition of the patient will permit. The highly intelligent husband of the lady, who by long and costly experience has become almost an expert in surgery, assures me that not for eighteen months have the affected parts looked so nice, clean, and promising as at present, and this I can readily understand from the truly wonderful and speedy change they underwent under my own eyes. In using the methylanilin for surgical purposes, care should be taken to employ a preparation free from arsenic.

644 LEXINGTON AVENUE, June 24, 1890.

ARIZONA AS A HEALTH-RESORT.[1]

BY C. L. G. ANDERSON, M.D.

LATE ASSISTANT SURGEON, U. S. ARMY.

THE purport of this paper is to call the attention of the medical profession to the super-eminent advantages which Arizona offers as a health-resort. Arizona is situated in the southwestern corner of the United States, between the 31st and 37th degrees of latitude, and extends from the 109th degree of longitude westward to the Colorado, representing an area of 114,000 square miles.

It is located between the convergence of the Sierra Nevada and Rocky Mountain ranges, and forms the larger portion of the southern extremity of the arid belt in the United States. The territory presents evidences of all the agencies of nature. Fire and water, convulsion and erosion, upheaval and depression, have left their impress upon the face of the country.

Arizona is surrounded by regions equally waterless. The proximity of the Pacific would indicate considerable moisture, but most of the humidity from that source is precipitated upon the western slope of the Sierra Madre Mountains, in Southern California, and what little gets over them is disseminated by the burning sands of the Mogave and Yuma deserts before reaching the territory. The loss of the humidity is compensated for by the protection from the fogs and winds of the California coast.

Our condition of health or unhealth depends more upon the state of the atmosphere than is generally recognized. I believe that the climate of Arizona presents every degree of elevation, temperature, and humidity necessary for restoration and maintenance of health. This claim may not appear so overdrawn if you recall the fact that the territory is fourteen times as large as the State of New Jersey. Let us indicate some of the diseases benefited by climate, and see if we cannot find antidotal conditions for most of this class of ailments within the confines of Arizona. Probably all the bodily functions are modified to a greater or lesser extent by the different factors which enter into the formation of climate, and, as disease is but a perversion of function, it follows that it must also be affected thereby. But it is mainly for diseases of the air-passages that we order a change of climate. Many of the numerous neuroses may be cured or alleviated by finding harmonious surroundings. Some heart troubles are also much benefited by proper climate. Many renal disorders could be treated to greater advantage if we could place the patient under atmospheric conditions where the burden of the excretion of water and salts was thrown upon other organs.

In that large class of diseases where more than one organ is involved—as the heart, lungs, and kidneys—a climate may be found which would produce a compensation and partial interchange of functions.

In the present unformulated state of climatological therapeutics, it is to phthisis alone to which we refer when we speak of climatic treatment, and it is the disease particularly in question in this communication. A fitting climate does more good in this disease than all other treatment combined, perhaps producing in some cases a cure.

Imperial in extent, it is impossible to generalize about Arizona, so we will treat our subject under several heads.

[1] Read at the second meeting of the Washington County Medical Society, Hagerstown, Md., April 9, 1890.

Arizona, like all Gaul, may be divided into three parts:

I. A mountain portion.

II. A valley portion.

III. A plateau portion.

This corresponds to the appropriate classification of the Mexican regions made by Hernando Cortés, into *tierra fria*, *tierra caliente*, and *tierra templada*—cold, warm, and temperate regions.

I. The mountion portion is composed of isolated mountain masses, arising principally from the plateau, representing an elevation of eight thousand feet and upward, and may be dismissed from our consideration, as the conditions of rarefaction and cold are not usually desirable.

II. The Colorado River drains the whole of Arizona, and the general trend of the drainage is toward Yuma, in the southwestern corner of the territory. This being its lowest point, we will enter the territory here and follow the natural rise of the land upward.

The town of Yuma is situated just below the confluence of the Colorado and Gila Rivers. Here

> "Vertical, the sun
> Darts on the head direct his forceful rays,
> . . . . . .
> And Cancer reddens with the solar blaze."

If it is your fortune to reach the place in July, with temperature 112° F. in your stuffy sleeper at midnight, you will surely sympathize with the poor soldier who died here and met with such a cool reception in the other world, and appreciate the appropriateness of the designation *calida fornax*—fiery furnace—applied to this region by Cortés and his companions.

Yuma is about one hundred and seventy-five feet above the sea, with a total annual precipitation of but a few inches. Nevertheless, for eight months in the year the place is inviting enough if you want a warm, dry climate, near the sea-level. However, the valley portion (which comprises the southern half of the territory) has a much higher elevation, the general average being about two thousand feet. Phœnix (1,200 ft.), Fort McDowell (1,800 ft.), and Fort Lowell, near Tucson (2,500 ft.), we will select as typical locations. The meteorological reports from these stations indicate an annual range of temperature of from 30° to 110°, with a yearly mean of 68°. The total rainfall of the valley portion is about eight inches.

Snow never falls here. The soil is sandy and holds no moisture, but artesian borings will reach water in most of the valleys. Natural vegetation, except along the water-courses, is scanty and that of the desert; but where irrigation is applied, almost anything, from oranges to wheat, can be raised.

It is the land of sunshine, fruits, and flowers, and the home of the cacti. Geraniums become tree-like, and heliotropes clamber like grape-vines. Cattle breed all the year. Centenarians are comparatively common among the Mexicans and Indians. I have seen gray-headed squaws whose identity was obscured by as many wrinkles as Haggard's "She."

The air is nearly free from organic matter, and the few microbes present are rendered inert by the lack of moisture. The whole makes up a warm, dry climate, of moderate elevation. It is the best winter home for phthisis that I know of. For those whose hearts or nervous tension cannot stand a higher altitude, it is best the whole year.

Throughout the country are mineral and mud springs which have a local reputation for possessing curative properties.

Southern Arizona is the land of "Mañana," where one can lead a *dolce far niente* existence and not care whether school keeps or not.

"What men call gallantry, and the gods adultery," is not common because the climate is *not* sultry. It is a haven of rest for the society belle and the Wall Street man who have been living on their nerves. The one, in her hammock under the palms, will soon learn to handle her fan and *mantilla* with the indolent grace of a true *señorita*; while the latter will smoke his *cigarro* by the murmuring *acequia* and dream of the days when the fat *padres* ruled the land, while the slaving *peons* tilled the maize and carried in the gold from the mountains.

The three or four summer months are warm, it is true, occasionally reaching 118° or 120° F., but in spite of the temperature, sunstrokes are unknown. The temperature rises so high that the moisture is not able to keep up with it, thereby reducing the relative humidity and making the heat less intolerable and depressing than it often is in our Eastern cities.

Everybody sleeps out-doors during the hottest weather, and the thermometer usually falls enough at night to make sleep refreshing. A mosquito netting is generally sufficient covering, and if you sprinkle it well before using you will probably get through the night very comfortably.

III. Let us now ascend to the plateau region, which is north of the 34th parallel, and, roughly speaking, makes up the northern half of the territory. The altitude varies from five thousand feet to seven thousand feet. The ascent from the valleys is gradual at some places; at others, abrupt, giving at certain seasons Switzerland and the Riviera within a few hours travel on horseback. As we rise the air becomes cooler, and the cacti and mesquite are replaced by juniper and pines. Grass and other vegetation is more abundant. The pulse and respiration are increased, and the lips become dry. There will generally be a little systemic disturbance at first, upon reaching an elevation of six thousand feet, but when one has become accustomed to the new environment he will comprehend the pleasure of mere living. The appetite is increased, and sleep is oblivion. To pass one's entire existence in the effete East is to miss something good in life, and to finally die of crowd-poison. Northern Arizona is a general table-land from which the mountains arise in separate, circumscribed masses. The country is fairly well timbered, and the grass is at times abundant. The drainage of the naturally porous soil is enhanced by the valleys on one side, and the Grand Cañon on the other. Indeed, so perfect is it, that water cannot be reached by means of wells.

The air is bright and exhilarating, and the sun shines nearly every day in the year. The atmosphere is so clear and impalpable that at night

> "The heavens seem as near as our own mother's face is,
> And we think we could touch all the stars that we see."

Whipple Barracks (Prescott) and Fort Apache are both at an elevation of about six thousand feet. The records of the post hospitals at these posts show that the annual range of temperature is from 10° to 90°, and that the mean is 53° F. The annual precipitation will average sixteen inches. There are no well-defined wet and dry seasons. The heavy rains occur monthly in the winter, and the showers in the early summer.

Snow falls during the winter. It does not lie long on the open country, but will last a long time in the shade. The plateau is almost free from the wind and sand storms of the highlands of Colorado.

The researches of Schwann, Budd, Pasteur, Lister, Tyndall, Koch, and numerous others, have demonstrated that, at ordinary levels, the air is full of floating matter, that this matter is mainly organic, and that many of these organisms are the cause of, or intimately associated with, disease. It has also been shown that at an elevation of six thousand feet bacteria are practically absent. Furthermore, experiments in germ-culture teach us that they require a considerable degree of heat and moisture for their development and propagation. Now, in Northern Arizona the conditions are all unfavorable. The coolness, the low degree of humidity, and the high percentage of ozone make up an atmosphere extremely inimical to bacterial life.

The efficacy of rarefaction in some diseases is so well established that we construct ingenious cabinets to relieve the pressure of gravity; here we find nature doing it, and as in everything else, better than man can do. We bottle up oxygen and dole it out to our patients a few minutes a day; here they can bathe in it the whole year long. In fact, the air is a real aseptic and antimicrobic fluid freely invading and preserving every accessible part of the person. The general mortality is less, wounds heal by immediate union without a dressing, and the bodies of dead cattle literally dry up and blow away. I never met a case of phthisis in an old settler, and it is well known that tuberculosis is very rare among the Indians and Mexicans. It is always warm in the sunlight, even during the coldest days of winter.

Although the equability of temperature is not so great as in the valleys, the fall after sunset is more conducive to refreshing sleep, and gives a *tonus* which one does not get in the valleys.

As the low degree of humidity causes the heat in the valley portion to be supportable, so the same absence of moisture makes the cold less intense on the plateau. Perspiration does not collect upon the surface, thereby eliminating that ever-present danger of "catching cold," which is the basis of so many diseases and retards treatment so much.

Bleeders have no business here, as there is a tendency to hemorrhage from the mucous membranes. High-strung, nervous persons cannot stand the stimulating atmosphere. Women, on account of their finer nervous organization, are liable to neuralgia and insomnia. They are apt to suffer from dysmenorrhœa and ovarian pain.

Of course, if a patient is in the last stage of tubercular phthisis his place is at home. Cases not so far advanced, but in whom there is not enough lung-tissue left to breathe at this altitude, should be advised to seek the valleys. But the ordinary cases of consumption, which we usually see in the first stage, can be sent direct to Northern Arizona. If the general health is robust, if there is no laryngeal or bronchial irritability, and if the heart is equal to the added strain, these primary cases can remain on the plateau all the time. The average case, however, will do best by passing the three or four winter months in the valleys.

It is almost impossible to designate the exact points for each patient. Primary cases should be sent to Northern Arizona, and those further advanced to Southern Arizona, and all directed to seek the most favorable places after getting there.

The entire length of the plateau is crossed by the Atlantic and Pacific Railroad, while Southern Arizona is traversed by the Southern Pacific Railroad. Prescott, the capital of the territory, is the gem of the northern climatic zone, and Phœnix and Tucson are rival queens of the valley portion. These are good objective points, and all are reached by rail. Throughout the territory the accommodations for the entertainment of invalids are not so grand as in some other parts of the West, but, I believe, more desirable on that account. There are no mammoth hotels with their thousand guests and gilded cesspools.

If one can live on a ranch, or pass most of his time in the saddle, so much the better. Its remarkable formation and natural wonders, its ancient and mysterious history, and its superior climate, appeal to and stimulate every element of our nature, and make Arizona unexcelled as a health-resort for certain classes of disease.

Italian Dentists Must be Doctors of Medicine.—By a recent decree, everyone who wishes to practise dentistry and "phlebotomy" in Italy must henceforth have taken a legally recognized degree in medicine and surgery. Dentistry will, for the future, be taught in the surgical department of such medical faculties as possess the necessary equipment for the purpose.

THE NEEDLESS PRESCRIPTION OF SPECTACLES.[1]

By H. GIFFORD, M.D.,
OMAHA, NEB.

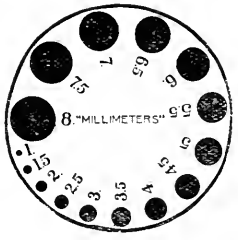
It is a common remark that the number of persons wearing spectacles, particularly at an early age, is rapidly increasing. The complaint is general with the laity that it is hardly possible to visit an oculist without having a pair of glasses prescribed. The oculists, on the other hand, explain that there are good reasons why more people should wear glasses than formerly. The increased use of the eyes which modern civilization demands, besides positively increasing the number of ocular defects, makes such as exist more difficult to bear without correction; moreover, our increased knowledge enables us to correct defects in a way that was formerly impossible, and forces us to correct slight errors which until recently were considered too insignificant to require attention. Valid as these reasons are, the writer is firmly convinced that the correction of slight errors of refraction has been carried to an unwarranted extreme, and that hundreds of persons are every week unnecessarily condemned to the use of spectacles. The observation of the practice of many oculists warrants the idea that in the bald and toothless future which some writers are predicting for the race, the great majority of persons over five years of age will also be bespectacled. For the adult, the inconvenience of having to wear glasses is unimportant, and with men this can also be said of the cosmetic effect. But with women, the disfigurement is certainly worth considering, and with young children glasses are a veritable infliction, both for patients and their parents.

It is unquestionable that a vast number of slight errors of refraction, and a considerable proportion of more pronounced ones, are borne for many years or for a lifetime without appreciable discomfort or detriment. The immense majority of eyes are ametropic, *i.e.*, theoretically abnormal; yet I think I am stating it mildly to say that it is the practice of the majority of oculists in this country, whenever a patient with 0.75 D to 1 D of hypermetropia, or 0.25 D to 0.5 D of astigmatism, comes complaining of eye symptoms not otherwise easily explained, to give him glasses for constant use if he will endure it. It is so rare to encounter an absolutely emmetropic eye, even in persons with no eye trouble, that we are seldom at a loss for some defect upon which to shift the blame. This defect may not be the cause of the difficulty, but if it is corrected and the symptoms disappear, the glasses get the credit for the change, and their use is continued often when they have accomplished nothing, or, at most, have tided over some emergency which might have been passed through without them. In this class of cases I have always started with the idea of avoiding the use of glasses if it can be done without permanent discomfort to the eye. If the patient is a child, my custom is always to tell the parents that, while glasses may be an eventual necessity, it may be possible to postpone their use for many years if the child be given light work for a time, and be made to think about the eyes as little as possible. Proper hygienic instructions are given, the most important points being to keep the work at sixteen to eighteen inches from the eye, and have the light properly arranged. If the child is a bookworm, more physical exercise is prescribed. Considerable patience and confidence in the oculist on the part of the parents is often required, for sometimes months are needed before the symptoms disappear entirely; but in the great majority of cases, with no more than one dioptric of hyperopia, or one-fourth of a dioptric of astigmatism in the vertical or horizontal meridian, my experience is that the trouble passes by, and that the need for glasses will probably not be felt again till the patient is past thirty-five, unless the occupation be very trying for the eyes. Of course, the difficulty of avoiding glasses increases with the degree of the defect, but with children

[1] Read before the Omaha Medical Club, February 7, 1890.

less than 2 D of hyperopia seldom requires correction, even for reading; while with young ones of five to eight years with no tendency to squint, much higher degrees may with advantage be left uncorrected for distance, because the refraction sometimes changes materially between the ages of five and ten years, the tendency being for the hyperopia to grow less; and if it does, the child, not having become wedded to its glasses, may go on for many years without having to use them except for reading.

Of course many cases occur where, on account of the nervous make-up, slight errors have to be corrected, and still oftener, particularly when there is temporarily an unusual strain on the eyes, as in young persons finishing school or preparing for college, or where the general system is run down from any cause, much may be accomplished by giving reading-glasses with the instruction to try leaving them off altogether after a time. With adults it is more difficult to avoid prescribing glasses, and here the objections to their use are less important. When they begin to complain of asthenopia, we generally have to correct the existing errors, for reading at least, unless the symptoms are due to some temporary stress or general derangement. It is, however, astonishing how often high degrees of astigmatism and hyperopia are born by adults without the slightest inconvenience beyond the poor vision or the necessity for the early use of reading-glasses which they cause. Indeed, a very high degree of astigmatism is less apt to cause asthenopia, when the eyes are not much used for close work, than a medium grade, probably because the subjects do not strain their ciliary muscles trying to see clearly, since the greatest effort of which they are capable exercises no appreciable effect upon the clearness of sight.



In these days, when so much emphasis is being laid upon the evil effects of eye strain, the question naturally arises whether in trying thus to avoid the inconvenience and disfigurement of glasses, we do not expose the eye to serious risk. My own conviction is that we do not. Many oculists are of a contrary opinion, and some speak assuredly of glaucoma and cataract from the non-correction of refractive errors, to say nothing of headaches, chorea, and epilepsy. For cataract and glaucoma it may be said that, while there are certain theoretical reasons why such non-correction might act as a predisposing cause, there is no good evidence that it does. If glaucoma is disproportionately common in hyperopic eyes, which is doubtful according to the recent statistics of Lozhetchnikoff (Abst. in *Ophthalmic Review*, October, 1889), it probably is so because hyperopia and a tendency to glaucoma are both results of a rigid sclera. If there is any connection between glaucoma and astigmatism, the latter is probably an effect rather than a cause; and if Schoen's theory of the influence of unsymmetrical ciliary contraction on the development of cataract were correct, we should certainly find cataract much more common with the educated classes, while, without having figures to support the idea, it seems to me the reverse obtains. If ametropia ever causes chorea or epilepsy, the connection is so rare as to be of no importance in this discussion. Headaches are, of course, frequently caused by slight refractive errors, and by avoiding a wholesale condemnation of children to the use of glasses, now and then a head will begin to ache later on in life; but there is little danger that some oculist will not have a chance to correct the error before serious trouble has resulted.

It should be observed that the foregoing does not apply to myopia. All myopes can, of course, have distant vision improved by glasses, and while, for the development of the mind, it is important that they should begin the use of distant glasses early in life, it is indifferent, simply for the health of the eyes, whether low degrees of myopia be corrected at all or not; but where the myopia is high enough to require reading to be brought closer to the eyes than eighteen inches, reading glasses should be prescribed, if for no other reason than to decrease the strain on the convergence, as this is probably the most important factor in causing myopia to develop and increase in eyes otherwise healthy.

In conclusion, I wish it clearly understood that I have no idea of disparaging the wonderful results sometimes obtained by the correction of slight degrees of ametropia. From a position of extreme scepticism regarding the effects of any glass of more than two metres focal distance, I have come to prescribe the quarter of a dioptric cylinder with very good results with some nervous men and women; though, considering the minimal optical effect of the glass and the temperament of the patients, I have often questioned whether the mental effect of the glasses was not greater than the physical; just as I doubt whether many of the wonderful results of graduated tenotomies are not achieved on the principle of the faith-cure. My object in writing the paper is simply to protest against the wholesale prescription of spectacles, particularly for children and young persons, with what seems to me to be insufficient cause.

Clinical Department.

THE TREATMENT OF ACUTE TONSILLITIS.

By EDWIN H. BIDWELL, M.D.,

VINELAND, N. J.

THE article by Dr. Hudson, of Stockton, Cal., in the MEDICAL RECORD of May 10, 1890, on "Veratrum Viride in Tonsillitis," is interesting not only because he makes a valuable contribution to the therapeutics of that frequent and hence important disease, but for its illustration of what we "average practitioners" have so often observed, namely, how writers, noted ones too sometimes, make everything appear so as to show off their own particular hobby in the very best possible light.

He says, speaking of the ordinary methods of treatment in tonsillitis, that "not more than ten per cent. recover without suppuration." Now "according to the best evidence attainable," as I read modern authors and my own experience, the antithesis, that not more than ten per cent. fail to terminate by resolution is certainly much nearer the truth. But I have no quarrel with Dr. Hudson, and must ask his indulgence that I may use his article as a text for some remarks which I feel prompted to make. I have nothing new, but my excuse for offering anything at all is the conviction that in the fashionable scramble after new things some of the old and true ones cannot be too often repeated lest we forget them entirely.

Boucsein, of Baltimore, in a careful study in the *Journal of the Medical Sciences*, October, 1889, expresses the opinion that acute follicular tonsillitis is a specific disease with an average course of three and one-half days, and that no remedy has any curative or abortive power. In the latter belief he is at variance with most authorities and, I think, mistaken. Morell Mackenzie (*Medical News*, January 26, 1889) considers guaiac "really specific" in the superficial (lacunar or follicular) form, and that it occasionally succeeds in aborting the deep (parenchymatous or suppurative) form, even when the inflamr a tion *begins*, as Trousseau pointed out that it sometimes does, in the substance of the gland. In his estimate of

the value of guaiac he is supported, more or less enthusiastically, according to their therapeutic temperaments, by many authors since the time of Ball, who introduced it as a specific, among them Agnew, Solis-Cohen, Bartholow, and Sajous.

Other remedies have also been highly vaunted—as cocaine by Dr. Haviland Hall and Boeckel (MEDICAL RECORD, October 1, 1887), salicylic acid, Haberkorn, (MEDICAL RECORD, September 28, 1889), bicarbonate of soda, boric acid, and strong solutions of nitrate of silver, by various authors, as local remedies, and aconite (Ringer) salve, antifebrin, salicylate of soda, and benzoate of soda internally. Boielmière (*Ann. Univ. Med. Sciences*, 1889, IV. E. 9) claims for this last to have cured seventy-five cases in an average of twenty hours, results quite as good as those of Dr. Hudson with veratrum viride. Unfortunately, benzoate of soda has not had as great success in the hands of others.

On the whole, the weight of authority is overwhelmingly in favor of guaiac, and with it, it seems to me, I have often had cures as rapid and remarkable as have ever been claimed by any one, and the general or gross results have been so eminently satisfactory that I have never been tempted to try any other remedy. I have had but one case within the last seven years, seen early, to go on to suppuration, and in that, in a very large fleshy man, the abscess of one tonsil opened spontaneously on the second day, and of the other on the third, so that he was virtually well on the fourth day from the inception of the attack. It has happened repeatedly that patients, who had previously "had their tonsils lanced" many times, recovered, without any necessity for that procedure, both pleasantly and rapidly.

Locally, I use only poultices on the outside of the throat, preferably a slice of fat pork, though flaxseed answers very well for those prejudiced against the vulgar pork, and in severe cases inhalations of steam. I give guaiac according to the following formula, first published, I believe, in the *Medical News*, August 11, 1883, and given also in Solis-Cohen's article on "Tonsillitis" in Pepper's "System," which I am accustomed to prescribe under the name of "Solis-Cohen's Gargle" or "Garg. Guaiac Comp."

℞. Tinctura guaiaci ammon.,
Tinctura cinchona comp.....āā fl. ʒ j.
Honey, strained..... fl. ʒ iij.
Saturated solution chlorate of potash ..... fl. ʒ xvj.

Of this the dose is a teaspoonful every two hours, hour, or half-hour, and I generally direct to both "gargle and swallow."

When gargling is difficult, and in young children, the dose is administered at intervals corresponding to the severity of the case without any attempt at gargling, and I am not quite sure but that it is equally efficient given in that way.

I frequently add aconite to this mixture; hereafter, in view of Dr. Hudson's recommendation, I shall substitute veratrum viride.

Mackenzie thinks lozenges more active than liquid preparations of guaiac, probably from more prolonged local action, and for this reason and for the greater convenience in dispensing in country practice, I have recently had Messrs. H. K. Mulford & Co., of Philadelphia, make me some compressed lozenges to correspond to the above mixture. Each contains four minims of ammoniated tincture of guaiac, four minims compound tincture of cinchona, and three grains of chlorate of potash, about equivalent to one drachm of the gargle, made up with licorice, aromatics, and sugar to a twenty-grain lozenge. These are useful and convenient also in many forms of sore throat, both acute and chronic, and in their special field, acute tonsillitis, they seem as efficient as the liquid gargle, though not by any means so pleasant to the taste.

In the differential diagnosis of the rheumatic form of tonsillitis I think no reliance can be placed upon a history of previous rheumatism or its absence. These cases are characterized by an amount of pain, fever, and dysphagia disproportionate to the objective symptoms. In them salicylate of soda in free and frequent doses is as satisfactory as guaiac in the more common form, which I think there are good reasons for believing a specific infectious disease, *not* of rheumatic origin.

A CASE OF DRY-GANGRENE, IN A BOY TWO AND A HALF YEARS OF AGE.

BY C. M. KELLEY, M.D.,
WINCHESTER, IND.

H. H. H—— was a boy two years and eight months of age, of robust and healthy constitution, having no dyscrasia nor unhealthy diathesis, and there being no hereditary disease in the family. He was never sick up to this time, active and vigorous.

On about June 10, 1889, my attention was called to a dark spot on the right foot, a simple discoloration of the skin on the dorsum of the foot, over the metatarsal joint of the little toe, about the size of a quarter of a dollar, or less. The skin was not broken, nor was there any sign of injury. It was just turned dark, showing death of the tissue to that extent without any external cause. There was no fever, and the boy made little complaint. I immediately recognized the seriousness of the condition, and began poulticing with the purpose of separating the dead from the healthy tissues. In the course of a few days it began to loosen, leaving a square, punched appearance of the edges, the black, dry centre still remaining attached at the bottom. About this time, June 15th or 16th, a line of red spots appeared along the inner side of the right leg (showing the course of poison), accompanied with fever, which in the course of a week reached 105° F., pulse, 160, and urine normal. The dark, dry centre still remaining I poulticed two or three days longer with yeast and charcoal poultice, and washed the gangrenous sore with bichloride solution. It still remaining firmly attached but not spreading, I had finally to dissect it away with a scalpel, and in a few days more all shreds of dead tissue had disappeared. Of all the physicians who saw him at this time almost all gave an unfavorable prognosis. After about one week the fever subsided, only to return again and again, as high as at first, for ten weeks. One peculiarity of the disease was an eruption. This eruption came in uniform shapes, in concentric rings, a red centre surrounded by a white ring, then a red ring, and so on. These were over the whole body, the legs, the trunk, the arms, and the face. Besides these regular shapes, there was a mottled, pied appearance of the skin, this was particularly marked about the face. This eruption came out with the fever, disappeared and reappeared with the fever each time, until the last few times, when the regular forms were absent, and only the mottled eruption appeared. The eruption always came when there was fever, and at no other time.

Another peculiar feature was the periods in which the fever recurred. On observation I found the fever recurred in exact periods of six days from the highest point of exascerbation one time to that of another, and lasted about two days.

Another peculiarity of the disease was the whitish, putty appearance of the stools. This I noticed after the first week, and it continued until convalescence was established, with tympanites of the bowels, which was extreme when the fever was high. The liver was slightly tender, and the cervical and inguinal glands were slightly enlarged. The flesh was always sore at the recurrence of fever. He ate heartily at all times, except during the highest fever, especially of meats.

The patient missed the paroxysms of fever after about ten weeks; he was somewhat pale and weak for a while, a flushed, mottled appearance now and then showing itself on the face, but now he is running about and seems to have made a good recovery. Quinine was used in large

doses until it was found to have no effect on the return of the fever, and Fowler's solution, calomel and syrup, iod. of iron, elix. iod. bromid, calcium comp. was also used, and a free purgation at the time of high fever and tympanites.

To recapitulate. this was a case of dry (senile) gangrene in a child two and a half years of age, followed by fever which recurred in regular periods of six days, with a peculiar characteristic eruption. (That this form of gangrene should appear in a child is very strange, and so is the subsequent history.

There are three kinds of gangrene—1, Acute, or moist; 2, senile, or dry; 3, contagious, or hospital, gangrene.

Three very interesting questions present themselves in this case:

1st. Why gangrene of this type, which is recognized by all authors as belonging essentially to old age, or in impaired feeble states of nutrition, should occur in a boy two and a half years of age, and especially in one so robust and healthy, is unaccountable. Wyeth says, "Dry gangrene may occur in any period of life; although children and adults are occasionally attacked, it is, in the vast majority of cases, a disease of the aged; hence it is called senile gangrene. Calcareous degeneration of the arteries," he says, "is given as a cause," but that could not be the case in this boy.

Hamilton says, "This variety of gangrene depends chiefly for its origin on those conditions peculiar to old age. They are essentially calcification of the muscular coats of the extreme arteries, united probably, in most cases, with a feeble action of the heart and with more or less atheroma of the larger vessels. Feeble action of the heart alone is competent to the production of a similar condition, as we see in examples which succeed low fevers or copious bleedings." I have heard of a case following scarlet fever, but in this case there had been no sickness; he had been in perfect health apparently." Gross says, "Mr. Pott was of the opinion that the disease was peculiar to old age, but subsequent experience has shown that it may occur at different periods of life, and within the last fifteen years a number of cases have been reported in which it occurred in children under ten years of age." He does not say he had seen the cases, and if a man of Gross's wide experience had not seen such cases, we must conclude it to be very rare.

Wyeth also says: "In many cases of dry gangrene there is no history of an injury. Symptoms of constitutional debility and general impairment of nutrition usually precede the local expression of the disease."

But there were neither of these conditions, neither calcification of the arteries, which could lead to embolism or thrombosis, nor enfeebled nutrition. and *no injury*. Thus, I am at a total loss to understand the origin of this case.

2d. Another feature in the case for which I am unable to assign any satisfactory explanation is the peculiar eruption, resembling some kinds of blood poison, especially those arising from animal bites.

3d. The periods of the fever. I have read of no fever which has a period of six days, and

4th. The nature of the poison, which causes an eruption, and fever recurring in exact periods of six days. There was undoubtedly a poison or a miasm capable of reproducing itself. I will only offer this suggestion that gangrene is caused by, or at least, produces a microbe, and that in this case the poison, of whatever nature, had the power to reproduce itself in periods of six days.

I should be glad to hear from the profession anywhere on this case.

Law against Adulteration in Russia.—The Russian Government has recently enacted some very stringent laws against the adulteration of food and drink. Any person guilty of adulterating any article of food will be liable to a fine of $200 or imprisonment for three months for the first offence, double this penalty for the second, and deprivation of all rights as a citizen for the third.

Progress of Medical Science.

Acute Primary Œdema of the Larynx.—Dr. Bernardo Martino reports the case of a girl, eighteen years of age, who was suffering from œdema of the larynx after "catching cold." The stenosis increased to such a point that it was thought best to transport the patient to the hospital. The dyspnœa finally became so urgent that tracheotomy was performed, the tube being left in for about two weeks. —*Revue de Laryngologie, d'Otologie, et de Rhinologie*, April 15, 1890.

The Treatment of Club-foot.—Orthopedic surgeons are by no means in accord as to the treatment of talipes, some advocating tenotomy in every case, others regarding operative measures as the last resort, and to be thought of only after a long trial of stretching. In the April number of the *American Journal of the Medical Sciences*, Dr. James K. Young reviews the testimony on either side, and comes to the conclusion that there is no arbitrary rule to be observed. He sums up the indications for one or the other method as follows: 1. Stretching should always be first employed in cases which are seen early. 2. Mild cases should always be treated by stretching. 3. Patients who object to the knife can be effectually cured by stretching, but it requires a longer time. 4. A tenotomized tendon is as strong as one that has been stretched. 5. In severe cases it is better to save time by tenotomy. 6. After-treatment to prevent relapse is quite as important as the operation itself.

Injections of Ether in Intestinal Obstruction.—Dr. Clausi reports two cases of intestinal obstruction relieved by rectal injections of ether. after all other methods had been tried and had failed. He employed an enema consisting of 12 gms. of sulphuric ether, 90 gms. of alcohol, and 300 gms. of fennel water. This injection was passed up as far as possible by means of a long cannula. At the beginning some colic was experienced, but soon evacuations followed, first of ether and then of fecal matters. The author attributes this result to the irritation of the peripheral nerve-terminations in the intestine, and the consequent increase in peristalsis, and also to the distention of the gut by the vapor of ether.—*Revue Générale de Clinique et de Thérapeutique*, No. 12, 1890.

Helianthus in Intermittent Fever.—Dr. Maminoff has obtained excellent results in certain cases of malaria in children from the use of helianthus annuus, a remedy recently proposed by Rosatchkoff, of St. Petersburg. The tincture of helianthus, one part in five, prepared from the flowers and bark of the plant, is a yellowish-green liquid, almost tasteless, and without odor. It may be administered to children in doses of from ten to twenty-five drops three or four times a day. The first case in which Maminoff made use of this tincture was in his own child, three years of age, who had contracted a quotidian fever that resisted the action of quinine and of Fowler's solution in pretty large doses. He then had recourse to the tincture of helianthus, and on the second day the access of fever was very sensibly reduced, while from the fourth day on it had disappeared entirely. The drug was continued for a week, or until the tumefaction and tenderness of the spleen had disappeared. A fresh paroxysm of fever appeared at the expiration of a month, but yielded at once to the helianthus, and never again returned. This success led the author to make a number of experiments with the remedy in his clinic of children's diseases, prescribing it in place of quinine for malarial fevers. In every instance the results of this mode of treatment were excellent, old cases especially yielding promptly in three or four days.—*Rivista Clinica e Terapeutica* May, 1890.

Vinegar often relieves at once the irritation produced by the bites of mosquitoes and other insects.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 5, 1890.

THE HYDROPHOBIA EPIDEMIC.

ONE needs to be but a very casual and careless reader of the daily papers to have had impressed upon his mind the fact that reports of cases of hydrophobia in man and beast are becoming alarmingly frequent. Dogs, horses, pigs, cats, men, women, and children, all over the country, are falling victims to the dread disease—if the newspapers are to be credited. Rabies has always existed in the world; indeed, one of the earliest terrors that appeals to the vivid imagination of the young child is that inspired by nursery tales of mad dogs, and many a timid girl, whose fears have been excited by these wicked stories, has been thrown into convulsions at the sight of a playful dog making friendly advances toward her. But the season for the nursery form of the disease, if we may so designate it, was always summer—the "dog days" being very appropriately selected as the time best fitted for the production of the malady, and the winter and spring were periods of safety. The present epidemic, however, has had no regard for tradition, but began early in the spring, or rather, late in the winter, and has steadily increased, regardless of meteorological conditions, since the establishment of the Pasteur institute. It is a curious fact that, in France and elsewhere, the prevalence of rabies has seemed to be closely dependent upon the rise of Pasteur institutes, and the more the institutes flourish the more numerous become the cases of hydrophobia among the community at large. Leaving aside the question of the existence of such a disease as hydrophobia, and whether, if it do exist, it may be prevented by Pasteur's method; or even admitting freely both these as actual and undisputed facts, it may well be asked how much the community gains by the creation in it of an institution for the treatment by preventive inoculations of rabies. Is the sum of human misery thereby diminished, or is it increased? Of course, the widest publicity is essential to the success of such an undertaking. People cannot avail themselves of a good thing unless they know of its existence, and they can never know of it so quickly as when they are informed through the medium of the daily press. Consequently, hardly a day passes that the papers do not contain accounts of alleged mad dogs, and of the setting out of their victims on a pilgrimage to the branch Mecca of Pasteurism in New York City. What is the effect of all this publicity? Can anyone doubt that it is to create needless alarm in many minds? Admitting the existence of hydrophobia as a distinct and well-defined disease, it is certainly one of exceeding rarity, and one may pass through a long professional life without seeing a single case in which the symptoms would suggest rabies. Yet, within the past six months we have heard of nothing so frequently as of hydrophobia. If our country were as thickly populated with abandoned curs as is the city of Constantinople itself (where, by the way, hydrophobia is said not to be recognized), we could not expect to have more cases of the disease than we are told that we have now. It cannot be doubted that many, if not all, of these cases are instances simply of fright, and that of those treated by preventive inoculations, so-called, not one in ten, at a very high estimate, is in the slightest danger of acquiring hydrophobia. The rest, and thousands of other people throughout the country, are simply frightened nearly to death. We have nothing against the Pasteur institute in this city, nor against the gentleman who has charge of it, and we believe that he is inspired with the highest motives and with a desire to popularize a method which he thinks will be of the greatest benefit to humanity; we will not argue as to the method itself, whether it accomplishes what is claimed for it or not; but we are firmly convinced that the establishment of such an institute in this country, with the popular agitation on the subject of hydrophobia to which it has given rise, is unfortunate, and has already been productive of an incalculable amount of mental anguish in those who may have been bitten by dogs, but who would never have given their simple wounds a second thought were it not for this newspaper notoriety.

FRANCE AND THE INTERNATIONAL CONGRESS.

IT is to be hoped that the physicians of France will not allow their political animosities to interfere with their attendance at the Berlin Congress this summer. At first, judging from the tone of the French medical press, it seemed as though no one calling himself a true Frenchman would dare to show himself at the Congress held in the enemy's capital city, but of late there has seemed to be a better spirit ruling, and we hope to hear of a large attendance at Berlin of representative French medical men. If there is not, it will not be for the lack of a cordial invitation from the German committees having charge of the arrangements for the meeting in Berlin. Nothing, indeed, could be more calculated to calm the natural irritation which was at first felt than the following from the pen of Virchow. He writes these words in a recent number of his *Arkiv*:

"Now that we have been called to offer our hospitality, we hope to see among us our confrères from all parts of the world. They may be certain that everything will be done to render both agreeable and profitable their sojourn in our city and in our country. We are ready to profit by their experience, and we should be happy if they might find among us something which would serve to instruct them. We shall not introduce into the scientific debates or into the social reunions anything which could make them feel out of place; we shall wound neither their political nor their religious sentiments. If we all respect each other as colleagues, and also a little as men, it will

be easy to overcome all differences. Medicine and humanity, they are the sole ends of the Congress. It is in this spirit that we have extended the invitation, and we hope that it will be accepted in the same spirit."

Certainly, if such a feeling animates all those who will assist at the meetings of the Congress, there need be no fear of any outburst of national antipathy. The French medical press association has taken up the question in a very sensible manner, and has issued a letter urging the physicians of the country to attend the Congress without hesitation or fear of meeting with any disagreeable experiences while in Berlin. The French government has also decided to send official delegates, and has detailed three army surgeons for that duty. There are, however, still some disaffected ones who have long memories and who are unable to reconcile Virchow's present pacific attitude with certain of his utterances in the past. He is said, for example, in an article written nearly twenty years ago, to have insulted the entire French nation collectively and individually. "Nations," he remarked, "often betray symptoms of disease in the same manner as individuals, and the affection which shows itself in the individual as an arrest of cerebral activity is at times met with over a large area as a psychic epidemic. A distinguished alienist of Southern Germany, Dr. Carl Stark, has come to similar conclusions from a study of recent events. [This was written in 1871.] He has shown, by a careful analysis of isolated and independent phenomena, that the mental condition of the French nation approaches in its general characteristics paralytic idiocy or emotional insanity."

This still rankles, absurd as it may appear, and many patriotic Frenchmen are loath to believe that any one who would write like that when under the influence of political animosity could ever repent or be softened by time. They neither forget nor forgive, and so hold themselves aloof from all participation in an international event from which they cannot exclude their enemy.

We believe, however, that better counsels will prevail, and that, despite the ill-feeling of a few individuals, there will be no boycott on the Congress. And this is well. The absence of the French members would seriously interfere with the success of the Congress, and it cannot but be the earnest wish of all who have the interest of the meeting at heart, that national jealousies shall not be allowed to intrude themselves into the domain of a science which knows no parties and no races, but only a common humanity.

THE AMERICAN MEDICAL COLLEGE ASSOCIATION.

THE permanent organization of this Association was effected, as announced in our columns at the time, in Nashville, on May 21st, during the annual session of the American Medical Association. There were nearly one hundred delegates present, representing fifty-seven colleges. The following are the rules of admission to the Association adopted by this convention, and which are to go into force within two years, or at the beginning of the college term of 1892–93:

"1. That the colleges shall require a graded course of instruction covering a period of not less than three courses of lectures of six months' duration each before graduation.

"2. That both oral and written examinations be required of all students.

"3. That a thorough course of laboratory instruction be maintained in chemistry, histology, and pathology.

"4. That there be a preliminary entrance examination consisting of:

"*a*. A composition written in English, of not less than two hundred words.

"*b*. The translation of easy Latin prose. (It is provided, however, that students be allowed one year to make up any deficiency in this examination.)

"*c*. An examination in Higher Arithmetics.

"*d*. An examination in Elementary Physics.

"It is provided, however, that candidates who are graduates or matriculates of normal schools supported by the different States be exempt from the provisions of this examination."

There can be but one opinion as to the nature of this change. It is distinctly an advance, and must tend to raise the standard of medical education throughout the entire country, affecting even those colleges which are not of the Association, forcing them to raise their own standard if they would compete with their neighbors. The good work of advancing medical culture is progressing surely, even if slowly, and the formation of the American Medical College Association is one of the signs of the times.

A STRANGE ACCIDENT.

DEATH sometimes seizes his victims in most queer and unexpected ways, but a stranger accident than one that happened not long ago in this city has seldom been recorded. A lady who had been suffering for several years from pulmonary trouble had been advised to try inhalations of hot air, and had purchased an apparatus for that purpose. In this apparatus is a thermometer, by means of which the patient is enabled to tell when the temperature is at the required height for the inhalations. One day the lady noticed a peculiar dryness of the throat coming on during the inhalation, but did not think much about it until it began to grow very uncomfortable. Then she inspected the apparatus, and found that there was a white powder in the inhaling tube. Removing this, she resumed the inhalations, but was soon obliged to desist on account of a sudden illness. This increased, and in spite of treatment the lady died the following day. Examination of the apparatus showed that the thermometer had broken, and the mercury falling out had been volatilized by the great heat and had caused fatal mercurial poisoning.

THE MEDICAL PROFESSION AGAIN DISREGARDED.

THE *Maryland Medical Journal* says: "Governor Jackson has permitted the constitutional time allowed for signing bills passed by the General Assembly to go by without giving his signature to the Medical Bill. The bill, therefore, fails to become a law. The profession and the people of Maryland are left for another period of two years without protection from the annual invasion

of medical quacks and incompetent practitioners squeezed out of other States into this State. His Excellency has shown a spirit of narrow-mindedness and of prejudice utterly unworthy of a cultivated and enlightened executive. He has treated the medical profession of Maryland with the most marked disrespect and disregard." This is only another illustration of the trifling weight attached by politicians to medical opinions and wishes.

If this were because these opinions are weak and these wishes impracticable or hurtful, such treatment might be endured as being of educational value. But this is not the case.

As politics are conducted in this country, the politicians and the organized bodies of voters alone have any influence. If the profession of Maryland would regain their self-respect and secure their just requests, let them organize and vote together. A body of men representing two thousand votes would amount to something in the eyes of the authorities, but a body of men simply representing an important idea are of no use in politics.

News of the Week.

Medical Education in Buenos Ayres.—In 1889 there were 430 medical students in the University at Buenos Ayres. Of these 66 were foreigners and 46 were women. Most of the latter were taking special courses in obstetrics, preparing themselves to practise rather as midwives than as physicians. There were 43 graduates in medicine in that year.

Needle-makers' Phthisis. — A sanitary physician at Stratford-on-Avon calls attention to the large mortality (seven per cent.) from phthisis among the workers in needle factories. He attributes the prevalence of the disease to the general insalubrity of the factory buildings, and more particularly to the insufficient ventilation of the work-rooms.

Deaths of South American Literary Men.—Within a period of five weeks five distinguished writers of Colombia have died. They are the publicist, Don Adriano Paez; the distinguished lawyer, Dr. Ramon Gomez; the Christian poet, Don Benjamin Periara Gambody; the writer and poet, Don Hermogenes Sarabia; and Dr. Florentino Vezga, the old and well known writer. The latter edited during a long period the *Diario de Cundinamarca*, and was author of a very interesting book on the study of botany in Colombia.

Dr. D. Gomperz, whom many students at Vienna will remember in the clinics for ear diseases under Politzer and Gruber, at the General Hospital, has established himself as a practitioner in diseases of the ear and nose in that city.

Dr. William Russell, of Utica, N. Y., died at his home in that city on June 27th, in the sixty-ninth year of his age. He was born in Glasgow, Scotland, and came to this country with his parents when he was eleven years of age. His early education was acquired at the Whitestown Seminary, and in 1841 he began the study of medicine with the late Dr. Whiting Smith, of Whitesboro. Later he pursued his professional studies at the Berkshire Medical College, Pittsfield, Mass., and after being graduated by that institution he took a post-graduate course at the New York College of Physicians and Surgeons. He was a member of the State Medical Society and of the American Medical Association.

A New Training School for Nurses.—St. Luke's Hospital Training School for Nurses in this city graduated its first class on June 28th. Six ladies received diplomas, and two of them will remain in the service of the hospital.

The International Congress.—The committee announces that all the hotels in Berlin have offered to entertain visitors to the Congress at reduced rates. Many furnished rooms are usually vacant during August, and they will be placed at the service of the committee. Information concerning the latter may be obtained at the office of the Congress, No. 19 Karlstrasse.

The Long Island College Hospital Training School for Nurses held its fourth commencement exercises on June 17th. Diplomas were granted to twenty-one graduates.

Dr. Charles W. Goucher, a well-known physician, died at Erie, Pa., June 23d, at the age of forty-two. He was a native of Greenville, Pa., and was a graduate of the Cleveland Medical College.

Leprosy in Dutch Guiana.—Leprosy is said to prevail extensively among the natives of Dutch Guiana. Three priests of the Redemptorist Order who work there are reported to have contracted the disorder, and one is dying at Batavia.

In Memory of Dr. Byford.—The one hundred and sixth meeting of the Chicago Gynecological Society was held on June 13th, at the Grand Pacific, its proceedings being entirely devoted to the memory of the late Dr. William H. Byford, one of the founders of the Society, and its first deceased Fellow.

Fiske Fund Prize.—The Trustees of the Fiske Fund Prize of the Rhode Island Medical Society have awarded a prize of three hundred dollars to Dr. Edward Martin and Dr. H. A. Hare, of Philadelphia, for an essay on "The Treatment of Wounds and Obstruction of the Intestines," and a prize of three hundred dollars to Dr. Philip Coombs Knapp, of Boston, for an essay on "The Pathology, Diagnosis, and Treatment of Intercranial Growths." For 1891 a premium of three hundred dollars is offered, under the usual conditions, for the best essay on "The Etiology, Pathology, and Treatment of Diseases of the Hip-joint."

The State Preliminary Examination of Medical Students.—It seems a somewhat unnecessary waste of time and energy for the State Board of Regents to send out elaborate circulars regarding the preliminary examination of medical students. The present amended law allows the medical student to spend three years in preparing for his preliminary examinations. In other words, the industrious student can have passed his final examinations in medicine before he passes his preliminary, to show that he is sufficiently educated to undertake the study of the medical sciences. The law is, of course, a

most ridiculous one. Still, the fact that it exists and that the regents are acting as though it possessed some force, will doubtless lead to its doing some good. The present law allows the Regents to excuse from these elementary examinations any candidate who possesses qualifications which the Regents consider and accept as fully equivalent. The Regents, at their recent meeting, after prolonged discussion, agreed upon equivalents to be accepted, and to-day print a circular carefully defining them. They are: "1. The completion of a full year's course of study in college. 2. A three year's course of study in a high school. 3. Any of the Regents' diplomas, which require from three to four years' study in a first-class high school. 4. Two studies each from the four groups into which the Regents' examinations are divided, viz., mathematics, science, language and literature, and history, philosophy, etc. 5. Any ten studies in which the Regents examine." The State is protected by the provision that certificates will be accepted only from institutions which have been examined and registered as maintaining the proper college or academic standard. The lowest equivalent accepted is for ten studies from the Regents' list, nearly all of which must of necessity be of higher grade than the seven required by the old law, so that those who are anxious to have the standard maintained are more than satisfied. But this system entirely removes the criticism on the old law, that a man who had led his class through the entire university course would be shut out from our law and medical schools as incompetent, if he had, from sickness or other reason, left college a few days before graduation. Regents' examinations for medical students will be held in the College of Physicians and Surgeons, in Fifty-ninth Street, September 23d, 24th, and 25th next. The questions given in New York will be employed in examinations held simultaneously in three other cities in the State.

Dr. Edward P. Davis has succeeded Dr. I. Minis Hays as editor of the *American Journal of the Medical Sciences.*

The Moor-bath a Humbug.—Many have wondered at the general fondness for moor-baths, often called mud-baths, in Germany, and various are the virtues ascribed to them. Dr. Jacob, of Cudowa, now declares they have no particular merit of any kind. A bath containing clay mud, and therefore devoid of the supposed chemically irritating substances in a "moor-bath," has exactly the same effect. Dr. Jacob considers that the concentrated essence of moor, kept at certain bathing establishments, is utterly useless, and the result of superstition.—*British Medical Journal.*

"**The Maryland Medical Journal**" celebrates the completion of its twenty-second volume by coming out in new type and a tasteful cover. We congratulate our esteemed contemporary upon its success, which is, furthermore, so well deserved.

The Cholera.—According to the latest cable reports, the number of new cases of cholera in Spain is decreasing, the province of Valencia, where the disease first appeared, being reported entirely free from it. On the other hand, new cases have been discovered in other parts of Spain and in some towns in the south of France.

"**El Shifa**" is the name of a medical journal which has been published for some years in Cairo, in the Arabic language. Dr. Grant Bey, to whom we are indebted for a recent issue of the journal, is a frequent contributor to its columns.

Typho-Malarial Fever in Texas.—Dr. George Dock, of Galveston, Tex., writes: "The report of my remarks in the discussion on the 'Continued Fevers of the South,' in the current number of the MEDICAL RECORD, contains some errors which I beg to have corrected in justice to the subject as well as myself. I did not say they never spoke of typho-malarial fever in Texas, for I have spoken in Texas of typho-malarial fever myself. What I did say was that in the *part of Texas where I practise* we do not have to exclude the malarial complication, or consider it, in the atypical fevers called by some typhoid, by others catarrhal, and as to the nature of which there is a difference of opinion. The statement attributed to me as to the treatment used is also erroneous, in that it gives the impression of a general practice where I spoke of single experiences, and I did not say one hundred and fifteen grains of antipyrine three times a day, but one hundred and twenty to one hundred and sixty grains in the course of a day, not of antipyrine (I spoke of 'antipyretics'), but of antifebrin."

The Surgeon-General of the Army, Dr. John Moore, will be retired on August 16th, on account of his reaching the age limit.

A new Medical College.—Our contemporary *The Times and Register* discourses lightly upon the new medical college at St. Louis. "We have long felt," it says, "that St. Louis really needed a new medical college. Last summer, as we rode along her streets, watching the Indians who had strolled in from the neighboring reservation, and dodging an occasional buffalo, we felt that another college was the one thing needful to make her citizens happy. And now it has come. The Marion-Sims College of Medicine has assumed shape, and presents itself with a faculty at least equal to any of those previously existing in St. Louis."

A Case of Osteomalacia Treated by Castration.—Dr. Albert Hoffa, of Würzburg, reports a case of osteomalacia treated by castration. The patient, aged thirty-one, had been four times pregnant, and in all the disease progressed. In the later pregnancies premature induction of labor had to be induced. The progressive nature of the disease induced Dr. Hoffa to remove the ovaries. Nine months after the operation, he was able to pronounce a permanent cure. He is of Fehling's opinion, that when the disease is steadily progressive, and the patient is in the child-bearing age, removal of the ovaries is demanded. —*Medical Press.*

The Vienna Poliklinik treated about forty thousand patients in 1889, and had 488 medical men in attendance. It receives a subvention of $70,000 from the Government, and $5,000 from the Emperor. From the above it appears that the post-graduate instruction in this city already exceeds that in Vienna. In our two institutions here, over eight hundred medical men are taught annually, while the dispensary and hospital resources of New York's "polikliniks" far exceed those of the Vienna institution.

The Central New York Medical Association on Coroners.—At a meeting of this society, held a short time ago in Rochester, the following resolutions were adopted :

"*Whereas*, It is part of the duties of a coroner to view all dangerously wounded persons and bodies found dead, to determine when, where, how, and in what manner such persons were wounded or came to their death ; and to cause inquests to be held if in his opinion a crime has been attempted ; and,

"*Whereas*, Such duties presuppose not only a knowledge of law and of legal processes, but also such a knowledge of anatomy, physiology, pathology, toxicology, and other allied sciences, as to qualify the coroner to determine between natural and criminal conditions ; and,

"*Whereas*, The office of coroner may be, and often is, held by men without legal or scientific qualifications ; therefore,

"*Resolved*, That in the judgment of the Central New York Medical Society, the laws relating to the office of coroner ought to be so changed as to render only competent men eligible to office, to the end that society may be better protected from attempted crime ; and

"*Resolved*, That the State Board of Charities, the Medical Society of the State of New York, and other societies interested in promoting the common weal, be requested to co-operate in the effort to accomplish the enactment of new laws relating to coroners as set forth in the foregoing resolutions."

The following officers were elected to serve for the ensuing year : *President*, Dr. Nathan Jacobson, of Syracuse ; *First Vice-President*, Dr. A. A. Hubbell, of Buffalo ; *Second Vice-President*, Dr. R. M. Cooley, of Oswego ; *Delegates to State Convention*, Drs. B. I. Preston, of Rochester, and C. H. Richmond, of Livonia.

A Contribution to the Subject of the Inheritance of Acquired Deformities.—There is at present much interest felt in the subject of heredity, and particularly of the views of Weismann and his school. The following communication, from a correspondent in St. Clairsville, O., whose name we cannot decipher, is timely. He writes :

"One of my patients has a black Newfoundland bitch—she had a long, bushy tail. The first several litters of pups were all like the mother, so far as having nice, long tails. Sometime since, an evil-disposed person shot off about half of her tail. Since then she has had several litters, and about one-half—just one-half—have short tails. What is the physiology of this case?"

Fees of Russian Physicians.—A correspondent of the *London Daily News* writes that the comparatively few Russian physicians who have attained a conspicuous reputation in their own country are paid even more handsomely than are many of the leading members of the British faculty. A few days ago a wealthy local notability at Odessa, Mr. P. S. Ralli, was operated upon for abscess in the hip by Dr. Sklifassofsky, of St. Petersburg. The operation was successfully performed within twenty minutes. The fee demanded and paid was 11,000 rubles, equivalent to £1,222. Incidentally a lady availed herself of Dr. Sklifassofsky's visit to Odessa to have an operation performed for cancer, for which she paid the operator 2,000 rubles, or £222. And yet, adds the correspondent, there are very many hard-working, conscientious, and skilful young practitioners busily engaged among the poorer classes of the populous provincial centres in Russia, whose yearly income does not exceed six or seven hundred rubles.

An Unfortunate Mistake in Dose.—A woman died not long ago in an English infirmary from an overdose of chloral, administered to her by the nurse on the doctor's order. The house surgeon found a bottle in the medicine closet, labelled "chloral, 1–2 solution." He, curiously enough, took this to mean thirty grains to the ounce, instead of thirty grains to the drachm, and prescribed accordingly. The patient had undergone an operation of resection of the intestine for strangulated hernia. She was doing very well, and would probably have recovered but for the surgeon's blunder.

Another Antiseptic, Sysol.—Dr. Gerlach, of Wiesbaden, has described the antiseptic power and advantages of sysol, which he has recently used with much success in Wiesbaden. As a bactericide it is more powerful than carbolic acid or creolin ; it is less poisonous than either of these two; and, finally, it is much cheaper than either. Sysol is not confined to use in closets, stools, washings, etc., but may be applied anywhere in the domain of medicine without any danger of poisoning or of discomfort. The active principle in sysol is the cresole. Gerlach believes that the drug will be found to be of real value, and that it will come into general use.

Five Years' Study for English Medical Students.—The General Medical Council has, at its session just concluded, recommended five years' study for medical students, and has formulated the definition of the five years' study which ought to be insisted on as follows :

"The fifth year shall be devoted to clinical work at one or more public hospitals or dispensaries recognized by any of the licensing bodies mentioned in Schedule A of the Medical Act (1858), provided that of this period six months may be passed as pupil to a legally qualified medical practitioner holding public appointments, or possessing such opportunities of imparting practical knowledge as may be satisfactory to the medical authorities."

This definition was carried, eighteen voting for and eight against.

Goat Vaccine.—M. Hervieux, in a lengthy paper on goat vaccine, read before the Académie de Médecine, comes to the following conclusions : A goat inoculated with cow's or human lymph furnishes lymph exactly similar to that of the cow ; vaccination direct from the goat succeeds as well as from the cow if the lymph is used quite fresh. Vaccination with goat's lymph, after it has been used to vaccinate a human subject, gives the same results as cow's lymph. In consequence of the discussion at the Academy of Medicine concerning goat's lymph, MM. Bertin and Picq asked that their *pli cacheté* deposited at the Academy last January, should be opened. Its contents may be summed up as follows : Tuberculosis may be transmitted to the human subject by cow's lymph. Goats, which are refractory to tuberculosis, should be substituted for cows ; the latter may be tuberculous, and yet be apparently in perfect health. MM. Bertin and Picq are continuing their experiments on the cow and the goat, to ascertain if tuberculosis can be transmitted either by virus or vaccine.—*British Medical Journal.*

Society Reports.

OHIO STATE MEDICAL SOCIETY.

Forty-fifth Annual Session, held at Columbus, June 4, 5, and 6, 1890.

J. McCURDY, M.D., PRESIDENT, IN THE CHAIR.

G. A. COLLAMORE, M.D., SECRETARY.

AFTER the opening session had been called to order by the President, the report of the Secretary was read. There had been nine deaths during the year out of a membership of 536.

The following papers were read:

"Errors of Refraction and Muscular Adjustment as Causes of Nervous Phenomena," by Dr. C. F. Clark, of Columbus; "Cleanliness in Eye Surgery," by Dr. B. L. Millikin, of Cleveland; "Surgery of the Knee-joint," by Dr. N. P. Dandridge, of Cincinnati. Dr. D. P. Allen, of Cleveland, showed a woman on whom he had done a successful nephrectomy.

A committee appointed to secure the more thorough organization of the State, reported in favor of making the members of all the county societies members of the State Society, as is done in Indiana. The recommendation was taken under consideration for one year and the committee continued.

Dr. N. Senn, of Milwaukee, on motion of Dr. R. HARVEY REED, of Mansfield, was elected an honorary member of the Society.

The Treatment of Compound Comminuted Fracture was the subject of a paper by Dr. S. L. McCURDY, of Dennison. The doctor exhibited a number of specimens, mostly of railroad injuries. He was a young man and advocated heroic surgery, saying that conservatism was only an excuse for ignorance and cowardice.

The "Rôle of the Microbe," was the subject of a wise paper by Dr. A. R. Smart, of Toledo. "The Etiology and Treatment of Pneumonia" was the subject treated of by Dr. S. P. Deahofe, of Potsdam; and "Vaginal Hysterectomy," by Dr. A. B. Carpenter, of Cleveland.

The President's Address, by Dr. J. McCURDY, of Youngstown, was on the subject, "The Care and Treatment of the Insane in this Country." He compared the history of the treatment of the insane in the various countries with that in the United States, which was to the great credit of the latter country. The Society of Friends, of Philadelphia, were the first to treat the insane kindly. He advised the taking of the incurable cases from the county poor-houses, and placing them in specially adapted institutions. He thought the law of New York State should be followed by others, viz., that all officers and attendants should be compelled to pass an examination, and not allowed to enter upon the work unless qualified. They should, when fully entered upon their duties, be placed upon the civil list and not subject to the caprices of politics. The asylums should be built on the cottage plan. One-half acre should be allowed to each inmate, and rural life encouraged. Medical societies should recognize, more than they have done, the study and treatment of the insane.

The Recent Epidemics of Diphtheria, Scarlet Fever, and La Grippe, at the "Sailors' and Soldiers' Orphans Home," at Xenia, was the subject of a paper by Dr. C. M. GALLOWAY, of Xenia. He thought the pages of history might be searched in vain for instances where the attendants in public institutions did more, better, and faithful work in epidemics of contagious diseases. The Home contained about 1,000 children, and the history of the rise and progress of the disease and the tireless efforts to dispel it was truly interesting. Children were again placed in certain cottages as often as three times, and still the epidemic returned. It was finally necessary to tear out the floors and plumbing. One young lady of Xenia volunteered to attend the little sufferers, and died of diphtheria. The disease could have been better handled had the hospital accommodations been greater.

The More Frequent Use of Chloroform in Obstetrics was the subject of a paper by Dr. J. F. BALDWIN, of Columbus. His conclusions were as follows: "Chloroform relieves pain. It shortens labor. It prevents shock. It prevents nervous and physical exhaustion. It reduces the liability to rupture of the cervix and perineum. It does not conduce, to any material degree, to post-partum hemorrhage. It does not affect the fœtus. It is absolutely safe when properly administered. He knew of no real contra-indications to its use, and urged that the boon be given to all women who ask it. He uses it chiefly in the second stage, carrying anæsthesia to the obstetrical degree merely; but at the last moment, when the head is distending the vulva and the agony is most extreme, he produces full anæsthesia. He spoke of the absurdity of the physician who, in the very acme of human suffering, would refuse the blessed unconsciousness that he quickly supplies for the mere drawing of a tooth or lancing of an abscess.

The First Porro Operation made in Ohio was the subject of a report made by Dr. J. F. BALDWIN, of Columbus. The patient was a dwarf, aged twenty-four, 47.5 inches in height, with an antero-posterior pelvic diameter of one and one-fourth inch. The operation was successful, both mother and child being saved. He also briefly reported three laparotomies made by him during the year, for various diseased conditions. Two of the operations were very difficult, but all the patients made excellent recoveries.

Carcinomata Mammæ was the subject of a paper by Dr. DUDLEY P. ALLEN, of Cleveland. The doctor believed that the common rules for diagnosis, and the prevailing advice as to operation, were bad. He insisted very strongly on the early operation. He thought we should not wait for immobility of axillary glands, for infiltration of tissue, and depression of nipple. He recommended, as a method of gaining access to the axillary space, the finding of the axillary vein and following it up. On early diagnosis and operation depends the success of the case.

Dr. W. W. PENNEL, of Fredericktown, used chloroform in the first, second, and third stages of labor. He thinks accidents are due to carelessness. In nine-tenths of the deaths from chloroform the fact of the matter is that the chloroformist does not attend to his business.

Puerperal Fever was the subject treated by Dr. G. H. COLVILLE, of Harrisville. He favored antiseptic precautions and time in the open air after having seen an infectious case, before going to a woman in confinement.

Dr. D. N. KINSMAN, of Columbus, did not believe in auto-inoculation, or that the disease was carried by scarlet fever. He believes that the poison is introduced through some abraded surface in the genital organs, through which it gains access to the blood. He advised thorough antiseptic treatment of the genitals. Cases formerly regarded as hopeless, under modern ideas of antisepsis, are cured.

The High Amputation of the Cervix vs. Total Extirpation of the Cervix, was the subject treated by Dr. T. A. REAMY, of Cincinnati. He argued that if we remove the whole uterus for epithelioma of the cervix, why not remove the vagina, bladder, and fimbriated extremities of the Fallopian tubes? Three cases in New York, post mortem, showed disease limited to the external os.

In two cases operated upon in Ohio the histological examination showed no evidences, whatever, of the existence of cancerous disease.

Intra-pelvic Surgery for the Relief of Inflammatory Diseases, was the subject of a paper by Dr. R. B. HALL, of Cincinnati. This paper was a report of one year's work, and a supplement to ten consecutive cases of abdominal section for the removal of the uterine appendages. The cases tabulated reached eighteen in number, and all but three had pus. All recovered. He wished to say that he could not make this report unmarred by a death, but that he had them where he could give them careful

after-treatment. It has been asserted that the after-treatment in these cases amounts to nothing. As a rule, they do not require long treatment, but need very careful attention for a few days at first. These operations are among the most trying in pelvic surgery. No exact estimate can be made, before opening the abdomen, of the gravity and extent of the complications to be met with in any given case. No man has a right to open the abdomen unless he is prepared for any emergency which might occur, and is competent to deal with the conditions found on the spur of the moment. He thought that all cases of prolonged chronic salpingitis should have a prolonged and systematic course of treatment. In many of the cases reported, it was impossible to separate the adhesions without bursting the pus-sac. In every case where this occurred, and in those where there was much bleeding, the abdominal cavity was washed out. Free washing-out of the abdominal cavity need not be feared, the heat relieves the shock. He has constantly employed it, when necessary, for three years, and has not seen a single case where it caused bad symptoms. The irrigation is continued till the water returns clear. Although all the cases recovered, many of them would not submit to an operation till *in extremis*. The doctor had seen four cases in consultation, and advised an operation, which was refused by the physician in charge and the friends of the patient, because an operation involved danger to life. All of these cases died within a few weeks from peritonitis, with every indication of ruptured pus-tubes. Three of these cases were proven by autopsy. There is danger in the so-called conservative, or let-alone plan, in cases where there is pus in the pelvis as well as in operation.

Cholecystotomy, report of a case, with exhibition of specimens, was the subject brought before the Society by DR. RUFUS B. HALL, of Cincinnati. The patient was a slender woman, thirty nine years of age, the mother of seven children, the youngest six years of age. Severe pain and vomiting of bile was followed by the jaundice and the observation of an enlargement in the region of the gall-bladder, which disappeared in about two weeks. It was not long till these symptoms returned. An operation was suggested, but refused. She went on and grew worse, falling from one hundred and fifteen to ninety pounds. When *in extremis*, and apparently dying, the doctor was called in consultation. An operation seemed the only ray of hope, and was suggested and consented to. The enlargement which was supposed to be the gall-bladder proved to be the liver. The gall-bladder was enlarged, and an obstruction was found caused by a stone in the common duct. Patient lost considerable blood, and it was necessary to reopen the wound. Patient survived the second operation. For fully a week her temperature was subnormal, once or more times during the twenty-four hours. The tube was removed on the sixteenth day, and on the twenty-first the sinus closed. The cholæmia rapidly disappeared. She complained of nausea but little after the third day, and vomited but twice after the operation was made. On the third day she retained liquid food, and after the fifth she had a ravenous appetite. The stools showed the presence of bile from the first movement, which was on the fourth day; on the twenty-eighth day she was able to go downstairs, and is now in her usual good health.

Shirt Studs and Teaspoons.—M. Périer, of Paris, has successfully performed gastrotomy on a man aged thirty-six, in order to extract a teaspoon from his stomach. M. Périer made the incision recommended by M. Labbe to the greater curvature. The patient is now in excellent health. A child aged ten, who swallowed a shirt stud made of bone, has also been successfully operated on by M. Périer. The foreign body became impacted in the upper part of the gullet, and M. Périer performed œsophagotomy and removed the stud. The child made an excellent recovery.

THE ILLINOIS STATE MEDICAL SOCIETY.

Fortieth Annual Meeting, held in Chicago, Ill., May 6, 7, and 8, 1890.

FIRST DAY, TUESDAY, MAY 6TH—MORNING SESSION.

THE Society convened in the First Methodist Episcopal Church, corner of Clark and Washington Streets, and was called to order by the President, DR. JOHN WRIGHT, of Clinton.

Prayer was offered by the REV. F. A. NOBLE, of Chicago.

The address of welcome in behalf of the local profession was delivered by DR. NORMAN BRIDGE, the response to which was made by DR. T. J. PITNER, of Jacksonville.

DR. C. W. EARLE, of Chicago, then presented the report of the Committee of Arrangements, which was a very elaborate one.

The Causes and Treatment of Pneumonia.—DR. J. M. G. CARTER, of Waukegan, Chairman of the Committee on the Practice of Medicine, read a paper on this subject, in which he said the question of etiology has given rise to considerable discussion, and in many minds to doubt. Six different varieties of bacteria had been mentioned by Bremmer as causing this disease, and others had been mentioned by later writers. The diplococcus of Fränkel had lately been shown to be present in most cases of pneumonia, especially croupous pneumonia. Wolff found it in ninety-four per cent. of the cases examined by him. Baumgarten thinks it is safe to assume a single sole cause for pneumonia. In Wolff's cases verification was established by cultures in more than half the cases. Monti examined the exuded fluid in twenty cases, with but one negative result. Sometimes the Fränkel diplococcus was found in company with other bacteria. In these cases of Monti, Friedlander's micrococcus was not seen. Inoculation of fifty-nine rabbits, while universally successful, produced typical pneumonia only when the sputum was introduced into the trachea. Inoculation under the skin produced septicæmia; into the pleura, pleurisy; into the pericardium, pericarditis. Inoculation of the dura mater of a dog produced meningitis and lobar pneumonia. Fränkel, Foa, Whittaker, and others have shown that the cause of pneumonia is not confined to the lungs, but invades other organs and tissues. Weichselbaum, Netter, Mircoli, and others have found the diplococcus after pneumonia in the ventricles of the brain, connective tissue of the mediastinum, the jugulum, above the clavicle, behind the œsophagus, in cavities about the nose, in the drum cavity and labyrinth of the ear. Tomasi, Golgi, and others believe pneumonia to be caused sometimes by malarial poison, and this view corresponds with that of physicians in the southern part of Illinois and other malarial districts in the United States, where this form of the disease is called "winter fever."

Dr. Carter said it must be admitted that the cause of pneumonia is not fully settled by the profession. It has not been proved that the bacillus is not a concomitant rather than a cause of the disease. In the present state of our knowledge the following indications for the treatment are clear: 1. To equalize the circulation and diminish the determination of blood to the lungs. 2. To reduce the temperature of the body. 3. To sustain the patient's strength. 4. To assist the mucous membranes and organs of secretion and excretion in the performance of their functions. 5. To allay pain. Petresco says digitalis may check pneumonia at the outset. It is of value in asthenic cases and when the heart is weak. Dr. Carter had not been favorably impressed with antipyrin, nor with antifebrin, and of late had not given them. Quinine is usually serviceable, and in malarial cases, essential, not only to reduce temperature, but also as a germicide and antiperiodic. Liebermeister advises blood-letting when there is œdema of the lungs, but Dr. Carter believes this may be avoided by blistering and the use of digitalis.

Bruckner has reported over seventy cases treated with tartar emetic with great success.

Dr. Carter regretted that there is no well-appointed laboratory for microscopical and physiological research in Chicago.

The Relation of Evolution to the Problem of Infectious Diseases.—Dr. G. Frank Lydston, of Chicago, read a volunteer paper on this subject. He said much of medical progress, for several decades past, has consisted in the isolation and differentiation of contagious diseases and their classification as specific entities. Dr. G. De Gorrequer Griffith, of London, England, published, several years ago, a theory of the unity of poisons, which implied that certain contagious diseases were identical in origin, and that their poisons could be developed through certain changes of a chemical character occurring in organic matter. Thus he recognizes two forms of scarlatina: 1. That contracted from a scarlatina patient, or through the medium of something that has been in contact or in communication with him. 2. That which has generated *de novo* from blood-poison, such as occurs in puerperal patients and in surgical cases (the "surgical scarlatina" of Paget) from deleterious matters absorbed or otherwise passed into the blood, and thence into the tissues of the body; or from noxious drains and sewers, or the ingestion of pernicious articles of drink or food, such as tainted water, milk, cream, decomposing animal or vegetable substances. We have, by evolution, the spontaneous generation of so-called specific poisons. Dr. Lydston does not hold that the germs themselves are spontaneously developed, for while such an event is perhaps possible, it is as yet disputed by the best scientific authorities. He claims that the poison of disease may be developed by the evolution of, and acquirement of, new and toxic properties by germs which were primarily innocuous.

The local venereal diseases, and in this category he included not only gonorrhœa and chancroid, but their congeners, such as herpes, balanitis, simple urethritis, etc., are among the best illustrations that we have of the poisons of infectious disease. The idea that gonorrhœa and chancroid are diseases which have been inseparable from the human species is certainly untenable. The origin of gonorrhœa and chancroid must necessarily be the same, if the evolutionary theory of their origin be correct.

The conditions which modify the results of the virus generated *de novo* in the human vagina are: 1, The age of the decomposition; 2, the degree of inflammation present; 3, the frequency of coitus; 4, the character of any semen or urethral discharges which may be deposited in the vagina; 5, the degree of cleanliness of the woman; 6, the amount and degree of virulency of the virus deposited upon the absorbent surface in another individual; 7, the cleanliness, local and constitutional condition, habits, and sexual hygiene of the recipient of the cultivated virus; 8, individual predisposition.

Afternoon Session.

Dr. W. O. Ensign, of Rutland, as soon as the Society had reconvened, took the chair, and President Wright proceeded to deliver his Annual Address, in which he advised the formation of country and district medical societies, and the co-operation of physicians throughout the State.

Dr. Wright then attacked the liquor traffic, and said that the State Board of Health should revoke the certificate of every physician known to use alcoholic liquor as a beverage.

Diagnosis of Typhoid Fever.—Dr. J. H. Wallace, of Monmouth, contributed a paper on this subject, in which he first protested against the common custom of calling all cases of continued fever typhoid. To be of practical importance to the patient our diagnosis must be based on the careful study and examination of the symptoms presented during life, and not on the phenomena observed after death. There are certain symptoms in common in all cases of typhoid fever. Thus, Dr. N. S. Davis says: "In classing all cases of continued fever under the head of typhoid and typhus, physicians ignore some of the plainest facts of clinical experience, and place in the same group cases essentially different in causation, symptoms, and pathological results. It remains therefore for us to detect minute differences."

The onset in typhoid fever, continued Dr. Wallace, is more gradual than that of any other fever, coming on insidiously and with premonitory symptoms. There is not that uniformity in the origin of typhoid fever which is found in intermittent, remittent, and yellow fevers, where we can give name to the cause and study the law of its diffusion. Cases of typhoid are met with at all seasons of the year, in all climates, and in all portions of the habitable globe, and among all varieties and nationalities of people. Two things are necessary to bring about a case of typhoid fever: 1, The poison; 2, the person liable to be poisoned. In all cases of suspicious typhoid fever an examination of the urine should be made, as Bright's disease, abscess of the kidneys, with blood-poisoning, occasions a deceptive likeness to typhoid fever. Wilson says that the most marked changes in the secretions from the kidneys is found to be interstitial or diffuse nephritis, probably of septic origin. Dunn regards our present knowledge inadequate to the solution of the question as to the part played by micro-organic ferments in the causation of the disease. One of Da Costa's diagnostic indications is the duration of the fever, he asserting that it lasts fully three weeks, and very frequently much longer.

The next thing in order was the report of the Special Committee on Diseases of Children.

Vaginal Irritation as a Cause of Bladder Symptoms in Young Girls.—Dr. Katharine Miller, of Lincoln, read a paper on this subject. More common even than enuresis among girls is a form of irritability of the bladder, manifesting itself chiefly in an inability to retain the urine in the normal manner. It is often complained of in school-girls, who are obliged to leave the school-room, even between intermissions, in order to pass the urine, else the bladder, spasmodically contracting, empties itself in spite of every effort of restraint. Even with the promptest attention to its demands, these girls are occasionally subjected to the mortification of wetting their clothing. Oftentimes no complaint is made of any other symptom than this annoying vesical irritability. The condition is more common at the age of six to twelve or fourteen, but may, if untreated, persist indefinitely. Examination reveals an extremely sensitive and hyperæmic condition about the vaginal orifice, and further investigation will show the extension of this tenderness within the vagina. Often this latter investigation can only be made by the use of an anæsthetic, not only because of the small size of the parts, but because of their extreme sensitiveness. Whatever the cause, the treatment must be directed to the removal of the vaginitis, when the bladder will recover its tone. Cleanliness must be enjoined. Not only is careful washing needful, but warm hip-baths are of value. Soothing powders must be dusted on, the vulva being opened as far as possible, and children old enough to understand the aims of the procedure will generally submit to the application, at night, of a small pledget of absorbent cotton, wet with a healing lotion containing pinus canadensis, hamamelis, carbolic acid, or similar remedy diluted with thin boiled starch. Where the urine is normal, rhus aromatica has proved a valuable aid in controlling the habit of irritability of the bladder and relieving the symptoms, till the cause can be removed.

Four Cases of Disease of the Mastoid.—Dr. Robert Tilley, of Chicago, read a paper on the above subject, in which he said that Barker, of London, in a study of abscesses of the brain, states that three-fourths of the abscesses of the brain are in the temporo-sphenoidal lobes, and that nine-tenths of subdural abscesses are found in a

circle one inch and a half in diameter, with its centre one inch and a quarter behind, and one inch and a quarter above, the centre of the bony auditory meatus. It might be further said, remarked Dr. Tilley, that nearly all these abscesses originate from some disturbance in some part of the external auditory apparatus. As long as facts substantiate this statement, the study of mastoid affections will not cease to be interesting.

The report of the Committee on Revision of the Constitution was called for, and was presented by the Chairman, Dr. Thomas M. McIlvaine, of Peoria. The report embraced several changes, among which was dividing the scientific work of the Society into three sections, as follows: 1. Practice of medicine, materia medica, and therapeutics. 2. Surgery, ophthalmology and otology, dermatology and venereal diseases. 3. Obstetrics, gynecology, and diseases of children.

The proposed changes and recommendations, after considerable discussion, were adopted section by section, and then as a whole.

Evening Session.

The evening session was devoted to a discussion of the question, "What shall We Do with our Insane?" Dr. E. Ingals, of Chicago, opened the subject by a brief paper. He was followed by Judge Prendergast, Dr. R. S. Dewey, Superintendent of the Kankakee Insane Asylum, Dr. Corbus, of the State Board of Charities, and Dr. Sanger Brown, of Chicago.

On motion the Society adjourned, to meet Wednesday morning at 9.30.

Second Day, Wednesday, May 7th—Morning Session.

Dr. C. W. Earle, Chairman of the Committee of Arrangements, announced that immediately after adjournment at noon, the Society would repair to Kingsley's, where a lunch would be tendered to visiting members by the Faculty of the Chicago Post-Graduate Medical School.

The report of the Committee on Surgery was then read by its Chairman, Dr. F. C. Schaefer, of Chicago. He said: In scouring the field of surgery we are compelled to admit that antiseptic surgery is an established fact. Very few surgeons at the present time have the hardihood to treat wounds without some pretensions to antisepsis.

Sterilized Lint.—M. Regnier recommends lint sterilized at the temperature of 248° F. for surgical dressings, having himself used it in many operations of various kinds with as good results as with antiseptic dressings. A surgical dressing may be antiseptic, and yet not germicidal. It is then inhibitory in its action, it prevents the germs from passing through it into the wound; and such qualities Lister claims to have found in the double cyanide of mercury and zinc, and by means of experimentation he has succeeded in preparing a gauze charged with the double salt. He says the double cyanide requires about three thousand parts of blood to dissolve it. If, therefore, it is present in a gauze in the proportion of about three per cent., you will easily understand that blood-serum may soak through such a gauze time after time without washing the ingredient all out; so that it is a material which is admirably stored up in the dressing. That is one of its three great advantages, the others being that, while trustworthy as an antiseptic, it is completely unirritating; and under this we find that not only do wounds, the edges of which are brought accurately together, unite beautifully by first intention, but even granulating sores heal by the gradual process of cicatrization from the edges—heal by scabbing in a way that we have never seen under any other dressing.

The Surgical Treatment of Typhlitis.—The operation should not be performed until all inflammatory and other symptoms have quite subsided. The incision should be made obliquely from above downward and inward over the cæcal region, its lower extremity ending just external to the epigastric artery. The incision should not be made directly over the appendix, or over the dullest region. If it be so placed a number of adhesions will probably be encountered, and the demonstration of the peritoneal cavity might be difficult. The cæcum or the appendix might be actually adherent to the anterior abdominal wall. The incising of the peritoneum should, therefore, be conducted with the very greatest care. It is well that the parietal cut should open the abdomen at a point just beyond the diseased area, and where no adhesions exist. When the appendix and cæcum are exposed, the area of the operation should be cut off from the general abdominal cavity by sponges. If this plugging with sponges be well carried out, no blood should enter the peritoneal space. All adhesions should be divided by cutting; none should be "broken down." The latter measure is apt to tear the bowel, or, at least, to bare it of peritonitis. The appendix should be lightly clamped close to the cæcum, and should be divided about half an inch from that intestine; it should not be secured by a simple ligature. The mucous membrane should be united by many fine sutures, or by a continuous suture; then the divided outer walls of the process should be brought together by a second row of sutures; it is practically impossible to bring the serous coats together. To still further secure the orifice, the stump of the appendix might be lightly attached to any adjacent surface of the peritoneum. The abdominal wound should be closed; no drain is required.[1]

Perityphlitis Vermicularis always belongs to the province of surgery, and the following two points are proven: 1. That perityphlitis is always accompanied by a pus-cavity. 2. That with the present plan of treatment the patient is more liable to a recurrence of the disease.[2]

Other subjects upon which Dr. Schaefer commented at length were: Herniotomy, bone surgery, gastrostomy, gastro-enterostomy, etc.

Dr. J. A. Freeman, of Millington, read a paper on "Harrison's Operation for Enlargement of the Prostate Gland," which was followed by a contribution entitled "Surgical and Mechanical Therapeutics in Diseases usually treated by Medicines alone," by Dr. George N. Kreider, of Springfield.

He presented the following conclusions:

1. That mechanical and surgical measures are the most certain in our armamentarium, and are only now assuming their proper position.

2. That when called to see a case of disease, the first aim of the practitioner should be to determine by proper examination and research whether some mechanical or surgical appliance cannot be used in conjunction with, or in place of, medical treatment.

3. That the "do something" which this action implies will be more uniform in its results, more successful in its curative effects, and more pleasing to the patient than the "think something" treatment, which tries every medicine by turns and nothing long, and hopes for beneficial results.

4. That the ability to use exact appliances for the examination of patients and treatment of disease should be possessed by everyone attempting practice, and that this ability is only to be obtained by preliminary training and clinical instruction.

5. That treatment of disease in this manner has a tendency to elevate the profession in the eyes of the public, and to dissipate nonsensical sects which divide the profession and waste its energies.

Malignant Diseases of the Rectum.—The general discussion on this subject was opened by Dr. D. W. Graham, of Chicago, who made some remarks on clinical diagnosis. He said: We have a certain group of symptoms common to almost all organic diseases of the rectum. These consist of interference with the function of the bowel; more or less diarrhœa, watery in character, more or less blood and mucoid discharges mixed with

[1] Treves. [2] Murphy and Lee.

fecal matter, this condition alternating with constipation. Pain is present; there is a general disturbance of health, as well as a disturbed mental condition peculiar to this region. Along with these symptoms we may have tubercular or the ordinary dysenteric ulceration of the rectum, with cicatricial contraction resulting. We may have the results of true syphilis present, the ordinary gummy deposit, and the so-called syphilitic inflammation of the rectum, which causes the deposit and ulceration and thickening. The age of the patient is an important aid to diagnosis. The disease usually develops during or after middle life. A few cases, however, are on record where the disease developed in people of twenty years of age.

Palliative Treatment, by DR. E. P. COOK, of Mendota. The indications for palliative treatment of malignant diseases of the rectum are, to maintain the permeability of that portion of the intestinal canal and the solubility of the fæces, to prevent the accumulation of fæces above the diseased parts, to secure a free passage of fecal matter and gases from the gut, to retard and arrest development of the disease, and to relieve pain.

DR. C. TRUESDALE, of Rock Island, spoke on palliative operations and their relative merits. He said a constant result of malignant disease of the rectum is more or less stricture and resulting obstruction to the passage of fæces. The first palliative operation resorted to is usually urethral or rectal bougies, for the purpose of dilating any stricture or structures which may exist. When the conclusion is reached, however, that an operation for a radical cure is inadmissible, the less we meddle with the rectum the better. The only thing worthy of trial, in his opinion, is an occasional irrigation with some warm antiseptic solution, such as warm carbolized water, the latter acting not only as an antiseptic, but also as a sedative.

DR. JOHN E. OWENS, of Chicago, dwelt upon the radical operations and their relative merits. The operative treatment for cancer of the rectum may be briefly considered under two heads, viz.: *First*, colostomy, or the establishment of an artificial anus, or some modification of the operation for diverting the fæces from their passage through the rectum, and thus dispensing with this portion of the bowel as an active organ. *Second*, proctectomy, ablation, or excision of the rectum. Proctectomy is confined to the lower portion of the bowels. If not attended by an undue mortality, or followed by great disadvantages, it should take its stand as an established procedure. During the last two or three years Dr. Owens has advised all patients who have been operated upon for cancer to report to him every thirty days. In this way recurrence of the disease can be dealt with promptly.

Senile Prostatic Enlargements.—The discussion on this subject was opened by Dr. Edmund Andrews, of Chicago, who illustrated his remarks.

Dr. Andrews was followed by Dr. A. E. Hoadley, of Chicago, who discussed in an able manner the indications for suprapubic and perineal method of approaching the prostate for operation.

"What are the Recognized Methods for Removing Prostatic Obstructions?" was the subject of Dr. C. Chenoweth, of Decatur.

Dr. A. B. Strong, of Chicago, read an interesting paper on the results of operations for the removal of prostatic obstruction.

AFTERNOON SESSION.

Renal Calculus.—The diagnosis was discussed at length by Dr. I. N. Danforth, of Chicago; the operation by Dr. J. Frank, of Chicago.

Perityphlitis.—Diagnosis was discussed by Dr. E. W. Lee, of Chicago; operative treatment, by Dr. Frank Andrews, of Chicago; when to operate, by Dr. J. B. Murphy, of Chicago.

DR. MURPHY said he had operated on seven cases in which there was neither fluctuation nor phlegmon in the abdominal wall, and in only one case did he fail to find pus. He was satisfied that there was almost entire absence of induration in this case, and could not be certain that pus was not present before making an operation. He operated from the ninth to the twenty-first day from the onset of the attack. In one case he failed to come directly on the abscess, but the pus emptied itself through the wound on the second day afterward. Usually, at the end of the fourth day symptoms of general peritonitis subside, and there can be felt a slight induration in the right iliac region; then is the time to operate. Dr. Murphy called attention to cases where there is only a small in duration in the ileo-cæcal region, with the accompanying symptoms of perityphlitis, before there is the slightest evidence of fluctuation or phlegmon in the abdominal wall. It is difficult to give the exact indications for the proper time to operate when the symptoms are slight, for both the patient and the surgeon are reluctant to resort to operative interference. As yet the number of cases operated on has been too small to lay down any definite rule; notwithstanding, it is Dr. Murphy's conviction that before many years every case of perityphlitis when diagnosed will be immediately opened, the appendix ligated, if possible, and amputated. This operation gives the only guarantee that a patient can have of safety from the impending danger of the disease, and security against its return. It must be remembered that in making the examination the greatest caution should be exercised in palpation and percussion, as he knew, from experience in making autopsies, that slight pressure can rupture the adhesions, and the whole contents of the pus-cavity escape into the peritoneum.

Treatment of Wounds.—This subject was opened by a brief paper, read by DR. D. A. K. STEELE, of Chicago, on the relative value of the different suture materials. He said, in selecting a suture material we are guided, by the light of modern surgical pathology, to select a material that is surgically clean—a substance that by suitable preparation and preservation has been rendered aseptic, *i.e.*, incapable of containing within itself micro-organisms that would carry infection from without into the tissues of the body. By a rigid adherence to this rule we are enabled to emulate Marcy, and close an aseptic wound by an aseptic suture aseptically applied.

"The Best Method for Preservation of the Different Suture Materials until Required for Use," was discussed by Dr. E. W. Andrews, of Chicago.

What is the Best Method of To-day for Preventing Infection of Operative Wounds? was the subject of DR. L. L. MCARTHUR, of Chicago. As patient, operator, instruments, sutures, and dressings may, any one of them, be a source of infection, Dr. McArthur devoted his attention to each. He ventured the statement that one-half of the primary wounds, under the present methods, are dressed aseptically at the time of operation, and then only become infected at the redressing. Operators under excitement are inclined to drop into careless habits, and proceed somewhat after the following fashion: They call for a questionable basin, and dropping into it an indefinite amount of carbolic acid, proceed to remove the dressings without any such formalities as we were satisfied were essential at first. Here is where the fallacy lies today. Too great carelessness at the redressing permits infection and encourages the sceptical in the belief that there is nothing in the principles of aseptic surgery. Before the old dressing is removed a stream of 1 to 1,000 should be ready and playing on the inner layer of gauze as it is being removed, and during the time of exposure of the wound. Having rendered the parts clean, they can best be kept so by providing, in addition to the regular dressing, a heavy dressing of absorbent cotton, not with the idea of catching discharge, but with the object of filtering the atmosphere which is to gain access to the wound through the dressings.

On motion the Society adjourned, and immediately repaired to Kinsley's, where a lunch was tendered by Dr. C. T. Parkes, of Chicago.

THIRD DAY, THURSDAY, MAY 8TH—MORNING SESSION.

Menthol in Diseases of the Air-passages.—DR. S. S. BISHOP, of Chicago, read a paper on this subject. He had used it considerably in a variety of diseases, and believes its remedial properties entitle it to an important place in the work of general practitioners and specialists alike. A five or ten per cent. solution is as strong as patients generally will bear without discomfort.

Stricture of the Œsophagus.—DR. E. F. INGALS, of Chicago, read a paper on this subject, which, he says, is met with more frequently in men than in women, and usually occurs in early life. It is not infrequent among children, and a few congenital cases have been observed. Strictures resulting from swallowing hot or acrid fluids are usually found at the upper part of the tube, just back of the cricoid cartilage. Next in frequency is the lower portion of the tube, near the cardiac orifice of the stomach. The stricture may be single or multiple. He reported thirteen cases.

Anosmia.—DR. JOHN E. RHODES, of Chicago, read a paper on this subject. He said no treatment has been suggested that will relieve a case of true anosmia. If dependent upon local conditions, as deformity of nasal structure, excessive hypertrophy, or nasal polypi, surgical measures may result in complete or at least partial relief.

Report of the Committee on Obstetrics.—This report was presented by the Chairman, Dr. J. S. Miller, of Peoria, which was a *résumé* of recent progress. It was followed by papers on "The Logic of Progressive Midwifery," by Dr. B. H. Harris, of Groveland, and the "Parturient State," by Dr. Lucinda H. Corr, of Carlinville.

Adenoid Hypertrophy in the Naso-pharynx.—DR. W. E. CASSELBERRY, of Chicago, read a paper on this subject. He said, in multiplicity of cases, gravity of consequences, facility of operative treatment, and brilliancy of results, the disease which is invariably known as adenoid hypertrophy in the naso-pharynx may be said to outrank any other affection of the upper respiratory tract. For pronounced hypertrophy the only satisfactory method of treatment is removal by surgical means.

The report of the Committee on Gynecology was next called for, and was presented by its Chairman, Dr. L. A. Malone, of Jacksonville. DR. MALONE gave a *résumé* of the work done in gynecology, as offered through the medium of medical journals, societies, monographs, etc.

Dysmenorrhœa.—Most happy results have been gained by the use of the steel dilator in this affection, dilating the cervix from three-fourths to one and one-fourth inch, antiseptic precautions having been taken. Goodell has employed this treatment in three hundred and twenty-two cases, without any serious mishaps, with almost invariable and permanent relief.

Tubes and Ovaries.—Abdominal surgery has been in the past few years a fertile field for operation. The sacred precincts of the peritoneal cavity, which but a few years ago none but the boldest dared to enter, have now become the fit arena for even novices to operate in. Since Lawson Tait electrified the world by his wonderful successes, emulators have become numerous everywhere. There is scarcely a hamlet in the United States to-day where may not be found at least one who has opened a woman's belly and erected a tombstone to the memory of his daring. All sorts of mental disturbances and neuralgias have been made a pretext for the operation. Dr. Malone had seen normal ovaries offered as a justification for their removal, the patient being a hystero-epileptic.

Constipation and its Relation to Pelvic Disease in Young Women.—DR. ELIZA H. ROOT, of Chicago, read a paper on this subject. Constipation, long continued, gives rise to a train of symptoms that present themselves for relief in the daily practice of every active physician; nor does he find any one cause of ill health so difficult to remove. It is an active factor in the production of pelvic disease in women; for, where endocervicitis and even retroversion exist, rapid improvement is made as soon as constipation is relieved. The causes of constipation are varied and arise in childhood from faulty diet, dress, and neglect of elimination. It occurs at the time of puberty when the transition from girl to womanhood gives rise to faulty nutrition and consequent relaxation of all the body tissues. Pelvic disease results from constipation through pressure. The filled and distended sigmoid flexure and rectum press upon blood-vessels, nerves, and muscles, exerting direct and reflex influences upon the functional activity of the whole economy. Dr. Root reported three interesting cases.

AFTERNOON SESSION.

Dr. Mary H. Thompson, of Chicago, read a paper entitled, "A Few Interesting Cases in Gynecology," which was followed by a contribution on "The Prevention of Puerperal Mastitis," by Dr. Ellen M. Heise, of Canton.

Hysterectomy in Malignant Diseases of the Uterus.—DR. F. H. MARTIN, of Chicago, read a paper on this subject. The operator reported five successful cases operated upon during the last year. His conclusions were: 1. Seek to make an early diagnosis of this dread disease. 2. When the diagnosis is made, operate early, selecting vaginal hysterectomy as the operation calculated to give the best results. 3. The legitimate future immediate mortality of this operation in the hands of experts will be as low as high amputation. 4. The ultimate curative results with vaginal hysterectomy must of necessity be the best that it is possible to obtain by operative procedure. 5. Vaginal hysterectomy is indicated in all cases of cancer of the uterus where it seems possible to get beyond the diseased tissue. 6. Choose the open operation; ligate the base of the broad ligament with strong silk, and secure its upper two-thirds with lock-forceps.

Dr. D. A. K. Steele at this juncture exhibited a patient upon whom he had operated for osteosarcoma of the right scapula.

Following this was the report of the Committee on Drugs and Medicine, Dr. John A. Robison, of Chicago, Chairman. DR. ROBISON took for his subject the "Treatment of Phthisis Pulmonalis." He said that the therapeusis in each case must be planned according to the patient, his social relations, his environments, his wealth, and the judgment of the physician. He presented for consideration the hygienic, climatic, medicinal, dietetic, and surgical treatment of the affection. Under the head of hygienic treatment he tabulated the following means: Respiration exercises, or deep breathing; breathing pure air; gymnastic exercises; sufficient rest and sleep; daily baths; dressing properly. With regard to the climatic treatment, he said that the practice of sending patients away indiscriminately is deplorable, as each case must be carefully studied, and the resort be chosen according to the individual temperament, stage of the disease, wealth, and social habits of the patient. A mountain climate is advisable in all cases where there is threatened phthisis with a strong hereditary predisposition, or where there is poor thoracic development. The warm and moist climates, such as the sea-coast or sea-voyages, are most suitable for phthisical patients of an excitable and nervous type, or those suffering from insomnia or bronchitis. The warm and dry climates are best suited to sufferers from phthisis who have heart disease or albuminuria. Surgically, there was every reason to believe that drainage antiseptically of lung cavities will be successfully done in the future. Dennison, of Denver, reports several cases in which drainage promoted cures.

Other papers which were read are as follows: "Opium in Disease," by Dr. C. E. Davis, of El Paso; "Catalpa Speciosa," by Dr. J. Schneck, of Mt. Carmel; "Relation of Eye Strain to Headache and other Nervous Affections," by Dr. F. C. Hotz, of Chicago; "Empyema of Antrum of Highmore," by Dr. R. Brown, of Chicago; "Treatment of Posterior Turbinated Hypertrophy," by Dr.

A. E. Prince, of Jacksonville; "Correction of Slighter Forms of Astigmatism," by Dr. Gardner, of Chicago; "Relation of Nasal Diseases to General Disturbances of Health," by Dr. H. Gradle, of Chicago; "Diseases of Children—Diphtheria, Intestinal Obstruction," by Dr. R. J. Mitchell, of Girard; "A Rational Method of Treating Rotary Lateral Curvatures of the Spine," by Dr. Charles F. Stillman, of Chicago.

Officers for 1891.—*President*, Dr. J. P. Mathews, of Carlinville; *First Vice-President*, Dr. C. C. Hunt, of Dixon; *Second Vice-President*, Dr. F. C. Schaefer, of Chicago; *Permanent Secretary*, Dr. D. W. Graham, of Chicago; *Treasurer*, Dr. T. M. McIlvaine, of Peoria; *Assistant Secretary*, Dr. George N. Kreider, of Springfield.

On motion the Society adjourned, to meet in Springfield, third Tuesday in May, 1891.

Correspondence.

IN THE HEART OF THE NEW SOUTH.

LETTER FROM BIRMINGHAM, ALA.

(From our Special Correspondent.)

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It is not always necessary for a Gothamite to cross the wide ocean in order to "see sights" combining the elements of novelty, interest, and entertainment. New York is so well known to possess many of the features of European towns that she is often sneeringly referred to as the most un-American city in the United States. The metropolis may, indeed, be likened to a tangled web of many-colored skeins, not all silk either. For small pains you can find in her vast cosmopolitan make-up representatives of every known continent, besides that scattering minority which hails from nowhere in particular. This mince-pie heterogeneousness of our city is clearly reflected in her medical life. We have Chinese physicians among us. (One of them died the other day, in the prime of life. An Irish widow and two children, one black, the other yellowish, survive him.) Turkish doctors are in our midst and out of it. We lack not the classic Greek, the emetic Tartar, the high-cheeked Scandinavian, and his modest friend from Gaul. With us African medical men are no rarity—and what is more, they manage to speak the vernacular far more intelligibly than our over-abundant British, Irish, German, and Italian importations. Like crude sugar, these medical raw materials are on the free list of the McKinley bill. And like crude sugar, you might not care to have them with your tea, before passing them through a native refinery.

But, all the same, New York is America, even professionally speaking, though possibly not yet to the same extent that Paris is France.

The New South.—But the "New South," of which we have all heard so much lately, the "Great South," which in neuropathic boom-paroxysms has already out-wested the West—that surely is American—core, backbone, marrow, and all.

Well, sir, the American place where I have my American washing "done up," down here, on the American plan, is presided over by a grinning Celestial, whose aide-de-wash is a buxom black lassie, whose right bower is an Irishman from Indiany, bedad. And this giddy triumvirate is skilfully aided and abetted by a one-eyed Italian with an unadulterated squaw for helpmate. For downright unmitigated Americanism, this quintuple alliance of the clothes-line deserves the ginger-snap every time; and probably gets it, too. For whenever I put on anything that has been in that Birmingham, Ala., New South laundry, something snaps, and a low, mellow voice may be heard to softly murmur, "Ginger!" This may seem fancy, but it is a fact, sir, a melancholy fact. As for the polyglotism involved in getting the dirt on your collar and pair of cuffs glossed over, it would be bewildering to any ordinary linguist. But a RECORD man doesn't shy at anything short of a night-call at the free-lunch counter.

It is a few weeks ago that, in response to an urgent professional summons from a New York family, I hurriedly packed my medical grip-sack and started southward for Birmingham. It will be my privilege to reproduce for your readers a few of the impressions made there on the camera (lucida?) of my sensory apparatus. The instantaneous process is now so much in vogue that I have no hesitation in claiming considerable truthfulness for my pen-pictures.

Birmingham.—What I will have to say, however, may not apply to the entire section below Mason and Dixon's line known as the New South, but it certainly refers to the Birmingham region, where I have spent most of my time. It soon forces itself upon the attention of the stranger here that the people have no mean opinion of their place and of themselves. In the aggressive enterprise of the "boom which has come to stay," Birmingham, the Magic City, reminds a Northerner far more of the eager bustle of a Western town, than of the languid indolence of the typical South, especially as depicted in modern works of fiction. There may be a simple reason for all this. The real Southerner is apparently not in the ascendant here. Of course there is no dearth of "Colonels" and "Majors," and high and low employ the pleasing "Howdy," in place of our more prolix Northern form of salutation. But nevertheless the outsiders, the *immigres*, the new arrivals, *i.e.*, the pioneer class, preponderate by large odds over the old native element.

A recent issue of the leading Birmingham paper, *The Age-Herald* (presumably so called on account of its youthful New York namesake), serenely informs the Birminghamites and their suburban friends, the rest of the world, that "Birmingham is the central city of all the South. Kentucky and Florida, Virginia and Texas, can come together here as at no other point. It is, by right of location and railroad facilities, the common meeting-ground of *twelve States*. Everybody wants to come to Birmingham. All the religious bodies, all the secret societies, all the railroad people want to meet here, and want to meet so badly that they come in spite of the halls we haven't got."

The engaging modesty of this touching sentiment finds echo in the daily utterance of all the nomad residents here. There are no real residers, in the Northern sense. All come and go by the month, the week, or the day, occasionally even by the year.

The Race-Problem Solved.—Nobody ever visits the South without forthwith solving the race-problem. How the hydra-headed monster manages to retain even mediocre vitality in face of its persistent solution, especially by Northern transients, will have to occupy the serious attention of future historians. Of course your correspondent, following imperative footprints, has also solved this ever-present problem. Here is his solution, and may Heaven forgive him if the smack of frivolousness should stand in the way of its immediate adoption: "Trade the nigger off for a yellow pup. Take the pup to the edge of the world. Drop him. And then see to it that he stays dropped." *Probatum est.*

There can be no valid objection to this rather radical method. For, have we not told the Chinaman that he must stay at home? Have we not cheated the only true American, the Indian, out of his birthright, and spurned his piteous appeals for more humane treatment? Then why this apotheosis of the African? He is more alien to the Caucasian than the Malay or the Red Man. Let him return to his native soil and clime, yes, let him climb.

The Practice of Medicine in the South.—Having thus disposed of the most perplexing problem of modern times, we can now profitably turn to the practice of medicine in the South. This appears to me very like the same occupation at home. If there are no far-famed leaders of the profession in Birmingham, they neverthe-

less have men who are called in consultation, and those who never do more than the calling. So, too, do they have big doctors and little doctors; those who are ever haunted by the dreadful secret of their own pre-eminence, as well as that subfamily of "Docs" who are not yet as macrocephalic as they will be a little later on, especially in the estimation of themselves; those who belong to the common, every-day, plenty-good-enough-for-me variety of practitioner, who sometimes hits a nail on the head, and more sometimes doesn't. They have doctors with horses and conveyances, and those without any awe-inspiring appurtenances. They have freshly hatched specialists, with bits of vitelline membrane and shell still fondly clinging to their puny persons, tell-taling the hoary ripeness of their experience. Besides these modern abortions they have the truly venerable humbugs, the fashionable quacks, the "orfully busy" general practitioners, itinerant pile-doctors, and those vagrants who modestly advertise as "lately of the Polyclinic." They have the statuesque frowners and the lubricated smilers, the man who is *suaviter in* his *modo* dealing with all womankind, and proportionately *fortiter in re*gard to the size of his bills. They have the doctor who never speaks at the medical society, and was never known to publish anything at all, and his friend across the way who always speaks, and always says what has been already better said, and who was never known to leave anything unpublished, especially the cases he thinks he has seen, and those matters which he believes he knows.

"Mein Liebchen, was willst du noch mehr?"

The only *avis medicalis* I have not yet run across down here is the top lofty potentate-professor. But though professors come low nowadays, we must have them. It is a matter of time merely, when they will erupt in this torrid zone, and then the mushroom will kindly step to the rear, and a little lively, too, please. Won't he, though?

In other words, they have just about what we have, only a trifle more so, because their medical laws are so strict; and perhaps, also, owing to the absence of a partisan board of health, there being only one party in the South.

Plenty of Doctors in Birmingham.—There is certainly no lack of doctors in Birmingham and its suburbs. In an over-estimated population of 45,000, they count at least one hundred and twenty-five men who expect to get a living out of medicine. And I am credibly informed that quite a formidable proportion of this professional light brigade, with counter-prescribing druggists to right of them, in front of them, etc., never get much beyond the expectant stage of earning their bread and butter.

Now, it is not a bad plan, in my opinion, to let some of our myriad "college-fodder" doctors stew in their own expectations. When they have stewed long enough to be thoroughly well-done, their children will probably choose a less over-populated calling, and one that requires more of an outlay in money, brains, and time than medical "diploma-getting" does nowadays. To borrow a suggestion from practical politics, my motto would be: "Turn the professors out," and "let the doctors in." So long as the "Dr. with a diploma" is such a cheap and plentiful commodity, the "Dr. without a diploma" will remain at his present premium. That ought to make good smoking for some people's pipes. And not a few pipes either, nor yet ten leagues away from home.

One thing is certain, the doctors don't go to Birmingham for their health. They go there for the boom which was, and, in a measure, still is. They go there because they have heard that all the New South doctors are on them ache. Nevertheless, after a due consideration of present chances and prospects, my advice to the young physician about to locate in Birmingham, is identical with *Punch's* counsel to the man about to marry, viz., Don't.

An Undue Proportion of Cripples.—It struck me, however, that there was an undue proportion of cripples, chiefly colored, round about this neighborhood, and doubtless the right kind of an aseptic surgeon could reap a rich harvest here. A few successful extensions, subtractions, infractions (in osseous, not legal parlance), and similarly mysterious doings, that constitute the black art of modern much-mixed orthopædology, would soon establish a medical man's fame on so firm a footing that his pocket-book would speedily cease limping after his money-spending desires. Sounds quite millennial, does it not, from a physician's point of view? According to the well-known adage, it's the early splint that captures the pocket-book.

Common Types of Men and Women.—It is unavoidable, of course, that I should say a few words about common types of men and women. The advent of Barnum (who had not visited this section of the South for over fifteen years) thronged Birmingham with the entire walkable and transportable population of a radius of at least fifty miles. The way some of them came would surely have suggested novel pictures to the artists of our comic journals. Yet these vast crowds of intermingling blacks and whites, though easily inclined to boisterous hilarity, rough pleasantries, and as the day waned, waxing more and more bibulous (as we are all apt to wax), were at least as well behaved as any metropolitan crowd, under similar provocation. The circus afforded me an excellent opportunity to observe fair specimens of rural and city mankind, as well as woman-and-child-kind.

As regards the men, they looked pretty much like men do all over this country, when wholly engaged in the single-minded pursuit of every money-making advantage. I can dismiss the men without further comment than the now firmly settled conviction, that the ubiquitous "Mayjaw" and "Coynal" really are—ubiquitous.

As for the women. May God forgive me if I pronounce a slander upon the fair sex. But the women here don't "look right." I have read recently, and I believe it, that "native beauty as developed in America is the outgrowth of such heterogeneous elements, such a conglomeration of nationalities, the interfusion of so many races and types, that any attempt to classify or even account for it, save as American, is futile. It is undeniable that climatic influences, freedom from old-world measures of restraint, and the diversity of our scenery, are forces which have contrived, unconsciously but effectively, to produce indigenous types."

Well, the indigenous type here is peculiar to the verge of the pathological. The women are almost all thin, haggard of feature, anxious, and apparently careworn in countenance. At twenty-five they look more wrinkled, sallow, and worn than they do home at forty. Many of them positively seem cachectic. You could readily fancy having found a colony where mammary carcinoma had become epidemic, and where wholesale amputation of the female breasts had become a matter of public safety, without, however, having successfully stamped out the dreadful visitation or eliminated the prevailing cachexia.

A large proportion of the babies and children also look more like the puny, under-fed products of our reeking tenements, than the plump denizens of a healthful provincial town. I understand that the servant question is held responsible for some of this mischief. Wet-nurses are hard to obtain. The mothers are willing enough, but generally find themselves in much the same fix that confronted the cherubim, when politely asked by St. Cecilia to be seated. They said: "*Avec plaisir, madame, mais nous n'avons pas de quoi.*"

The Gallinipper.—From humanity we get by an easy gradation to the gallinipper, who is a much maligned and greatly overrated institution of the New South. It is true, he is big, black, and burly. He comes early and often, and he stays late, just like the front-parlor young man, when getting engaged. At first sight you are inclined to enter into diplomatic negotiations with him, to treat his liberal advances with distinguished consideration. But on better acquaintance you learn to cut him dead, and cut him quick. There is no Wagner in him, only the timid tinkle

of Italian opera. He has no vim. A tired rattlesnake might hold more poison. Alongside of a fairly healthy Jersey mosquito (and there are such), or even a South-Side Long Islander, just out of his teens, he is a pale figment of fiction, an Eden Musée imitation, a thing to be laughed at and treated with scorn, or gentlest slaps at most. For a real tap would spoil him quicker than a keg of lager on a close election. In the prime of his manhood the gallinipper is as weak as circus-lemonade. When he has done his level worst you feel tempted to exclaim: "Oh, galli, where is thy sting! Oh, nipper, where is thy misery." Gentlemen of the South, if you *must* know what a well bred family of mosquitoes can do, take a Long Branch dude with his bold aquiline profile in *haut relief*. Take him after a mild evening stroll on what was formerly a beach. Take him, and inspect him, and if you like, keep him, though the chances are you won't want to long. But as for bites—the most exacting artist could easily utilize him for a study in wheal-life.

Sapienti sat. And so will I.

EDMUND CHARLES WENDT, M.D.

BIRMINGHAM, ALA., June, 1890.

THE AGE OF GRADUATION FOR MEDICAL STUDENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your editorial in the last issue of your valued paper, you comment unfavorably upon the advanced age that most of those graduating at Harvard must attain, and recommend that those students who contemplate studying medicine after graduation should go to some small college, where they may obtain a degree when they are twenty years of age. For my part, I believe that your contention that two or three and twenty is too old to begin the study of medicine is well-founded, and, strange as it may appear, the Faculty of Harvard College seem to take the same view of the matter; for they have voted to grant the bachelor's degree to students completing courses of study that can be accomplished in three years after matriculation. The Corporation of the College has approved this action of the Faculty, and the consent of the Board of Overseers is now all that is needed to make the action final. I dare say that the latter body will readily acquiesce. As the average age of entrance is about eighteen, a good student may easily graduate at one and twenty. And surely, Mr. Editor, a Harvard degree at twenty-one is greatly preferable to that of some small college at twenty. The prestige of the place alone, not to mention its fine laboratories and excellent appliances for the pursuit of natural history, chemistry, and other studies that are most essential to the prospective medical student, far outweigh the disadvantage of remaining in the university one year longer.

It seems only fair that you should give publicity to this action on the part of the governing boards at Harvard, partly on account of your own animadversions in the editorial spoken of, and because shortening the required course a year will prove a great boon to many students who cannot afford the money required for a four years' course.

Those not desiring to graduate in three years can of course take a longer time, or can, after taking the bachelor's degree, remain at the university and study for a higher degree.

Harvard is now taking the final steps toward making herself a true university, and I submit, Mr. Editor, that she deserves much credit for what she has done for the cause of higher education in America.

Respectfully yours,

R. C. NEWTON, M.D.

MONTCLAIR, N. J., June 18, 1890.

Generous Rivalry.—Generous rivalry is sometimes carried to such an extent in professional struggles, that the strivers are very apt even to give each other away.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 22 to June 28, 1890.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability, with permission to go beyond the limits of this division, and to apply for an extension of five months. Par. 1, S. O. 45, Division of the Pacific, San Francisco, Cal., June 13, 1890.

GREENLEAF, CHARLES R., Major and Surgeon. By direction of the Secretary of War, will attend the encampment of the Pennsylvania National Guard at Mount Gretna, Pa., from July 18 to July 26, 1890, for the purpose of accompanying the Surgeon-General of Pennsylvania in his inspection of the camp. Par. 11, S. O. 144, A. G. O., June 20, 1890.

KEEFER, FRANK R., of Pennsylvania. To be Assistant Surgeon, with the rank of First Lieutenant, June 6, 1890, vice Woodruff, promoted.

RAYMOND, THOMAS U., of Indiana. To be Assistant Surgeon, with the rank of First Lieutenant, June 6, 1890, vice Newton, resigned.

SNYDER, HENRY D., of Pennsylvania. To be Assistant Surgeon, with the rank of First Lieutenant, June 6, 1890, vice Wilson, resigned.

SMITH, ALLEN M., of New York. To be Assistant Surgeon, with the rank of First Lieutenant, June 6, 1890, vice Matthews, promoted.

HEYL, ASHTON B., of Pennsylvania. To be Assistant Surgeon, with the rank of First Lieutenant, June 6, 1890, vice Hall, promoted.

CLARK, JOSEPH T., of New York. To be Assistant Surgeon, with the rank of First Lieutenant, June 6, 1890, vice Porter, resigned.

CULBERTSON, HOWARD, Captain (Retired). Died June 18, 1890, at Zanesville, O.

BORDEN, WILLIAM C., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for three months and fifteen days, to take effect as soon as his services can be spared. Par. 11, S. O. 141, A. G. O., June 23, 1890.

SUTER, WILLIAM N., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for two months, to take effect August 6, 1890. Par. 3, S. O. 149, A. G. O., June 26, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 28, 1890.

PAGE, JOHN E., of Berryville, Va. Commissioned Assistant Surgeon in the Navy.

KENNEDY, ROBERT M., of Pottsville, Pa. Commissioned Assistant Surgeon in the Navy.

WHITFIELD, JAMES M., of Richmond, Va. Commissioned Assistant Surgeon in the Navy.

STONE, LEWIS H., Litchfield, Conn. Commissioned Assistant Surgeon in the Navy.

ATLER, LOUIS W., Assistant Surgeon. Detached from Marion and granted three months leave of absence.

Scotch Diagnoses.—According to the report of the Glasgow medical inspector, nearly eight per cent. of the persons sent to the fever hospital were found to have been incorrectly diagnosed, and of this number fifty-seven per cent. suffered from no contagious disease whatever.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 28, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	1
Scarlet fever	29	6
Cerebro-spinal meningitis	1	3
Measles	281	27
Diphtheria	99	27
Small-pox	0	0
Varicella	7	0
Pertussis	0	11

The International Congress in 1893.—There has been some talk of inviting the members of the International Congress to hold the next meeting in Chicago in 1893, during the progress of the world's fair there. As the Congress met in this country in 1887, and as there is still some uncertainty in the minds of many people outside of Chicago whether there will be a fair there at all, it hardly seems worth while to extend an invitation which will only be refused.

Exorcism of the Pest Demon in Japan.—Dr. C. H. H. Hall, of the United States Navy, in a series of notes upon certain medical customs of the Japanese, appearing in the *Sei-I Kwai Medical Journal*, speaks of the curious belief in the demon who causes epidemic diseases, and who seems to be a sort of enlarged and supernatural microbe. His name is Yaku-iin-no-kami, and his habit is to come and sit by the side of the sick person, much to the detriment of the latter. The method of driving away this evil spirit is, Dr. Hall writes, as follows: A kannushi, or Shinto priest, makes a preliminary visit to the sick-room to extract from the demon a promise that he will depart with him at his next visit. The priest returns on the following day, and, taking a seat near the patient, beseeches the evil spirit to come away with him. Meanwhile red rice (used only upon special occasions) has been placed at the patient's head, a *kago*, or inclosed litter, made with pine boughs, is brought in, and four men armed with flags or other weapons have entered and stationed themselves in the corners of the room to prevent the demon from taking refuge there. All are silent but the priest. When the prayer is ended, the patient's pillow is hurriedly thrown into the *kago* and the priest cries "All right now!" The *kago* is then hastily taken out into the street and the people within and without begin to shout and beat the air with swords, sticks, or anything at hand, while others beat upon drums and gongs. A procession is quickly formed, composed wholly of men, all of whom wear fillets and horns of twisted straw to keep the demon away from themselves. Banners, a drum, a bell, a flute, and a horn are carried. One man chants, as they move away, "What god are you bearing away?" The others reply in chorus, "The god of the pest we are bearing away!" then the drum, the bell, etc., are sounded. While the procession passes through the town all who are not taking part in the ceremony remain indoors, all houses along the way are carefully closed, and at the cross-streets are stationed men armed with swords who guard that street by cutting the air to right and left lest the demon escape by that way. The litter is borne to some retired spot between two towns, where it is left for a time and all who came with it run away, except the priest, who remains for half an hour to complete the exorcism by some sort of magic, after which the patient recovers. Those who carried the litter spend that night in prayer within a temple, and return home next day after a cold bath in the open air, lest they take the demon back with them. One *kago* is used in common by the town, the lightest case being visited first.

Four Children at a Birth.—A pretty well authenticated story comes from a Pennsylvania town concerning the birth of quadruplets to a woman in that place. The four children, all girls, have been baptized under the names of Agnes, Aloysia, Agatha, and Ada. The pictures of the children have been taken and are being sold for the benefit of the family. The unhappy father was somewhat consoled the other day by the receipt of the deeds of six town lots from a land company in Colorado, who have named certain streets of their town after the four children and their parents.

The Etiology of Jacksonian Epilepsy.—Since this form of disease was first described several conditions have been enumerated as giving rise to it, among others the occurrence of parasites in the brain, to which group belong two cases reported by Dr. Yamagiwa. The chief points noted in the author's examination of the bodies were: 1. Disseminated, circumscribed groups with worm ova, and mostly with inflammatory cells in the cortical substance of the brain. 2. Localization of these changes in the occipital, parietal, and central lobes. 3. New connective-tissue formation and round-cell infiltration around the foci of disease. 4. Thickening of the vessel-walls, especially of the adventitia, and obliteration of single twigs. 5. Foci of disease in the lungs, also with worm ova and inflammatory cells. As regards the nature of the mother of the ova, the author believes that they should be assigned to distomum pulmonale. His grounds for this are: (*a*) their size; (*b*) their form, since no human brain parasite has up to the present been described which lays such ellipsoidal ova as distomum pulmonale, or D. cerebrale, as this form may be called. The chief points in this case are as follows: A. Pathological. (1) Attacks of left-sided convulsions. (Later these became general, but always commenced and were stronger on the left side.) (2) Disturbances of sight in the left eye (the right slightly shared in this); indistinct vision, etc. (3) Proportionately slight paralysis of the extremities. B. Physiologically this case is interesting, in so far as it confirms the position of the centre of sight in the occipital lobes, and affords further proof of the relation between convulsions and cortical lesions. C. The occurrence of distomum as a new kind of brain parasite is interesting, especially in a region where distomum is so common as in Japan. D. Diagnostically and prognostically: in cases where patients are affected with disease of the lung due to distomum, the possibility should always be borne in mind that a worm or ova embolism may take place in the brain. It will also be a useful thing to examine the sputum for distomum ova when any person in a distomum region is affected with cortical epilepsy.—*Medical Recorder.*

Albuminuria Caused by Morphinism.—At the meeting of the Société Médicale des Hôpitaux on May 9th, Dr. Huchard pointed out (*L'Union Méd.*, No. 58) that the abuse of morphia sometimes causes albuminuria, which leads to death by uræmia. Levinstein has published seven such cases, and Dr. Huchard contributed three others, all fatal from uræmia. As to the connection between the renal disease and morphinism, Dr. Huchard suggested that it might be through the action of the poison on the medulla, or by long-continued diminution of arterial tension; for he has found that morphine lowers arterial tension considerably, thus favoring passive congestion in the organs, the kidney among others. According to him, whereas excessive arterial tension will ultimately bring about arterio-sclerosis, a persistent lowering of tension can lead to Bright's disease. Obviously, Dr. Huchard does not here speak of granular kidney, which is associated with high arterial tension.—*The Lancet.*

A Just Observation.—The man who remains abstemious where no liquor is to be had does not deserve much credit, but the man who is temperate when the sparkling champagne stands beside his plate merits our approbation.—*Journal of the American Medical Association*

AN EXPLANATION OF THE PHENOMENA OF IMMUNITY AND CONTAGION, BASED UPON THE ACTION OF PHYSICAL AND BIOLOGICAL LAWS.[1]

BY J. W. McLAUGHLIN, M.D.,
AUSTIN, TEX.

CONTAGION consists in the transmission of communicable diseases from one individual to another through the agencies of contagia, the efficient causes of all contagious diseases; these contagia may be communicated by contact, through the atmosphere, or from infected articles, fomites.

Immunity signifies that condition of the body which opposes the development of contagious processes. The principles involved in the causation of contagion and immunity, therefore, lie at the very foundation of all knowledge of those laws which control infectious diseases.

The importance and wide application of these principles, and the successful efforts which nature has made in concealing them from man's knowledge, have stimulated him to great and laborious investigations, and have resulted in the production of many ingenious theories.

This subject has occupied a large share of my attention for many years. From observing nature's methods in other departments of science—how, through the action of physical laws, physical results are obtained—the conviction grew upon me that this method furnished the key that would unlock our problem. The subject was so complex, the observed phenomena were apparently so diverse and even contradictory, that a long time elapsed before I was able to report any progress. In 1887 I published the first results which I obtained by this method.[2] Notwithstanding the subject was still very hazy at that time, I could see how the laws of wave-motion, when applied to the motion of organic molecules, would explain some of the phenomena of contagion, but the complete elucidation of the subject had not yet dawned upon me. Francis Galton says: "Few intellectual pleasures are more keen than those enjoyed by a person who, while he is occupied in some special inquiry, suddenly perceives that it admits of a wide generalization, and that his results hold good in previously unsuspected directions." While thinking over the phenomena of contagion and immunity, and the laws of wave-motion, the beautiful law of interference occurred to me, when it flashed over me that the application of this law to molecular wave motion completed the chain of evidence. I felt very much as I imagine did Archimedes when he sprang from his bath and ran naked, shouting "Eureka," through the streets of Syracuse.

Time will not allow an attempt to kaleidoscope the history and varied opinions regarding contagion; suffice it that in this, as in the evolution of other questions of science, the theories offered from time to time were based upon such information of the subject as was then known, and all possess some truth.

In the light of our present knowledge it can be safely asserted that contagium is a particulate substance; that it is capable, when suitably environed, of increasing itself indefinitely by multiplication of its particles; that in this increase it produces only its own kind, and does this as unerringly as do animal or vegetable species in their increase by generation. Thus a very small portion of small-pox virus or contagium, if inoculated under the skin of a susceptible person, will multiply and increase itself in the blood of this person, and pustules will form upon his body which will contain the same character of contagious substance, possessing the same distinctive properties, as that used in inoculation.

Or, a person with an infectious fever may infect a hundred or more persons with the same disease, transmitting to each one the amount and kind of contagium that he himself received at the time of his infection.

There is no known substance, neither a solid, a liquid, nor a gas, save and except a living organism, which is capable of increasing and multiplying its own kind in the manner thus described.

The striking similarity which is seen between fermentation and contagion has led many observers to believe that the latter, like the former process, is caused by microscopic organisms. As there are many kinds of fermentation, each kind resulting from the action of specific organisms—for example, alcoholic fermentation is caused by the yeast plant; acetic fermentation by the micrococcus aceti; butyric fermentation by the bacillus amblyobacter, etc.—so it is claimed that each specific infection has its specific bacterium or bacteria. I do not think that it can be maintained that only one species or variety of bacteria will produce a specific infection, for example, a specific infectious fever. It is well known that fermentation—alcoholic, acetic, or butyric—may result from the action of more than one kind of ferment or bacteria. Hence, if the analogy between fermentation and contagion is sound, there are grounds for believing that more than one kind of bacterium may cause a specific infection; for example, diphtheria, cholera, and other infections may each be caused by one or more kinds of bacteria.

A bacterium is a one-celled vegetable micro-organism or plant, which is so very small that the highest powers of the microscope are often needed to render it visible. It is composed of a complex substance called protoplasm, which Huxley has named "the physical basis of life." The cells have no visible nucleus, and may or may not have a limiting cell-covering.

All classifications of bacteria are provisional, yet it is convenient to arrange them according to their growth-forms as they are at present understood. When the cells group themselves singly or in masses, which are more or less characteristic, they are termed micrococci. Those growth-forms characterized by the cells being joined together end to end to form rods or spirals, are called bacilli or spirilla. When the vegetative cells or spores of future bacteria grow within the bodies of bacteria they are classed as endosporous varieties. On the contrary, when the spores are formed differently, that is, outside the bacteria, they are said to belong to the arthrosporous variety.

Those bacteria which find in other organisms alone conditions suitable for their growth and development are called parasitic bacteria, while those forms which live upon dead substances are called saprophytes. In whatever form or shape the bacteria are found, whether as cocci, rods, or spirals, they are always one-celled organisms; and however much these cells may resemble each other

[2] Etiology of Acute Infectious Diseases, Daniel's Medical Journal.

in their appearances, these resemblances cease to exist when we compare the character of work which these cells are capable of doing. Vegetable and animal cells differ in this respect among themselves as greatly as do the animal or vegetable substances composed of such cells. We are familiar with the various kinds of tissue-cells of which the human body is composed; we know that some of them are glandular and are connected with the secretion of bile, gastric juice, etc.; or in the separation from the blood of certain products of tissue metamorphosis; that others enter into the formation of the nervous system, and are connected with volition and motion, others form bone or cartilage or muscle, etc. Vow, the single-celled vegetable organisms known as bacteria differ as greatly among themselves in the character of work which they perform as do the tissue-cells of the human body. A few illustrations of this fact will not be amiss. We will briefly refer to the kind of work done by the micrococcus ureæ, the nitrifying bacteria, the bacteria of the mother of vinegar, the bacteria of lactic-acid fermentation, and the bacteria of the decomposition of proteids.

The micrococcus ureæ consists of round cells, microscopic in size, which may be formed singly or joined end to end like a string of beads; this organism converts urea into carbonate of ammonia; it is capable of doing this not only in the urine, but a pure culture of this organism will do the work just as readily if added to a solution of urea.

Micrococcus nitrificans consists also of small round cells. This organism or microbe converts the compounds of ammonia which are found in the soil, or added to it for fertilizing purposes, into saltpetre, which is appropriated by growing vegetation. It might appropriately be called the granger microbe, for through its influence the growing crops are enabled to utilize the ammonia compounds of the soil, which would be useless without this agency. A pure culture of this microbe, if added to an artificial nutrient solution containing compounds of ammonia, does its work as effectively as though it were at home in its native soil. Micrococcus aceti, another small round cell, is the agent by which alcohol is converted into acetic acid; the various methods used in the arts for the making of vinegar are based upon the power of this microbe of converting watery solutions of alcohol into acetic acid.

Micrococcus lacticus occurs in the form of minute cylindrical cells, and is the microbe chiefly concerned in the souring of milk, by converting the sugar it contains into lactic acid.

Bacillus amblyobacter is the microbe of butyric-acid fermentation. It vegetates in the form of slender cylindrical rods, and is one of the most widely diffused and important and varied in its powers of decomposition. In addition to the important part it plays in the manufacture of cheese, it is a specially active agent in destroying the cellulose of cell-membranes in the decomposition of decaying plants. In the process of rotting hemp, flax, and other textile plants, in order to obtain the fibres, this microbe plays the all-important part Van Tiegham attributes to this organism an important part in the nutrition of ruminant animals. He claims that it vegetates in their stomach and splits up the cellulose of their food into soluble products. For illustration of the bacterial decomposition of the proteids we will refer to the bacterium termo (the drum-stick bacillus of putrefaction). Its uses in the economy of nature—for example, in disposing of dead animals—are sufficiently apparent to require no specification. Were it not for this microbe it would be a serious matter to know how to dispose of dead bodies. If it was necessary many other examples of friendly microbes, those necessary to man's comfort or his safety, could be cited to illustrate the power which these organisms have of decomposing or splitting up many substances. It will be seen, however, from what has already been said, that there is a striking difference among these lowly cells as to the character of fermentation or kind of work which they are capable of doing; thus one variety causes acetic, another butyric, and yet another lactic acid fermentation.

One of the objects of this paper will be to establish as a fact that the principles involved in fermentation are the same, regardless of the exciting cause, and that the products of fermentation will largely depend on the molecular structure of the exciting ferment Before entering upon this subject I shall invite your attention to certain phenomena attending fermentation, and for illustration will describe that form which results in the production of alcohol. It is well known that vinous fermentation has for its ferment, or exciting cause, a one celled vegetable organism generally known as the yeast fungus, and that brewers' yeast is entirely composed of these cells. When, under suitable conditions, yeast is added to a solution of malt, called "wort," fermentation will ensue and alcohol will be the principal resulting product. One of the substances which the "wort" contains is sugar, and it is this sugar which the yeast-cells decompose and convert—at least ninety-five per cent. of it—into alcohol. The yeast-cells, like other organisms, multiply themselves by the generative act and thus increase in amount, so that the amount of yeast is a thousand-fold more at the end of fermentation than it was at the beginning. Alcohol, the principal product of vinous fermentation, is poisonous to the yeast-cells, and when, during the process of fermentation, a certain per cent. of alcohol is formed, fermentation at once ceases and cannot be re-established until the alcohol, or a considerable portion of it, is removed. That fermentation occurs only in contact with the yeast-cells, and does not result from a hypothetical enzyme secreted by them, is established in the following way: Divide the fermenting vat or vessel into two parts by a membranous diaphragm, so that no substance can pass from side to side except through the interstices of the membrane. Put your solution of malt equally into both sides, but put the yeast in one side only. Now, all soluble enzymes, or other soluble substances contained in the malt solution, can readily pass through the diaphragm by osmosis, from one side to the other, forward and backward, but the insoluble yeast-plants are confined strictly to the side into which they were placed. Under these circumstances fermentation has been found to occur only in that side of the vessel in which the yeast-cells have been placed. An interesting, and, for our purpose, an important, fact connected with this subject has been established by Oscar Brefeld, who, by a peculiar artifice, has so modified the yeast-cells in their structure that they can be made to grow and multiply in the solution of malt without producing a particle of alcohol;[1] the bearing of this fact upon one of the phenomena of contagion will become apparent further along. We are now prepared to point out the striking similarity in phenomena of fermentation, as set forth, and the phenomena of contagion.

Both are caused by one-celled vegetable organisms; these cells in each case are microscopic in size, and can be conveyed from place to place in various ways that will readily suggest themselves, and therefore require no special mention.

The cells of bacteria, like the cells of the yeast-plant, excite fermentation and decomposition when they are suitably environed. In the same manner that yeast-cells decompose sugar into alcohol, the cells of the micrococcus ureæ convert urea into carbonate of ammonia, the cells of the micrococcus nitrificans convert ammonia compounds into saltpetre, the cells of micrococcus lacticus convert sugar into lactic acid, and pathogenic bacteria-cells convert certain albuminoid molecules of the blood or tissues, of man and animals, into poisonous substances, ptomaïnes or toxines.

And again, as alcohol is poisonous to the yeast-cells and will arrest the fermentation which they excite, and by which it was produced, so ptomaïnes and toxines, the products of infection created by the cells of pathogenic bacteria, poison the bacteria which caused their exist-

[1] Fermentation, Encyclopædia Britannica.

ence, and arrest the fermentation or infection which gave them life.

And finally: As the yeast-cells can be so modified in their molecular structure that they can be caused to grow and multiply in malt solution without producing alcohol, in a similar manner the cells of some pathogenic bacteria can be so modified by "attenuation," in various ways, that they are not only made harmless to man, but become a vaccine by which protection from the virulent microbes may be secured.

In all the examples of fermentation which have been cited, or, as a matter of fact, in all fermentations or infections, the products resulting from these processes, whether it be carbonate of ammonia, acetic acid, saltpetre, lactic acid, alcohol, or ptomaïnes or toxines, are invariably caused by cells decomposing or splitting up certain substances contained in the nutritive solution.

It behooves us, then, to inquire into the mechanism of this wonderful little cell, and to ascertain how, or by what method, it is capable of doing this work. At the outset, let me say that there are many things pertaining to the life-history, physical structure, and mechanism of the cell which are not understood; in fact our knowledge of cell life and structure, beyond what is revealed by the microscope and chemistry, is very meagre. This subject offers an immense field for speculation and theory which has not lacked cultivation. When there are not sufficient facts with which to build a theory, speculation becomes necessary to complete the structure, and often answers an excellent purpose, provided it is constantly guided and limited by established laws of chemical and physical science, and provided, also, that the theory thus constructed is found to be competent to explain the phenomena connected with, and belonging to, the subject. Now, the theory of cell-action which I offer, although largely speculative, complies with the conditions just stated. For a better understanding of this theory I will premise its discussion by the following statement of physical laws:

An elementary substance is the simplest known condition of matter. An atom is the ultimate part of such substance.

A compound substance is composed of dissimilar atoms. A molecule is the smallest division of a compound substance which has the properties of the substance.

Each and every atom has a natural period of vibration from which it cannot be separated.

Force, the efficient cause of all physical phenomena, is motion—atomic, molecular, or molar. Attraction, light, heat, and electricity are manifestations, or modes, of one and the same force; they are co-ordinate and subject to the laws of transmutation of energy.

As atoms have their equivalents of motion—for example, their laws of attraction, repulsion, and combination—which are inseparable from them, it follows that, when atoms combine to form complex substances, each one carries into the combination its equivalent of force or motion; this may be modified by the motion of associate atoms, but is never lost, and when a dissolution of the compound takes place, the departing atoms carry with them the same amount and kind of motion which they had originally.

All atoms, whether combined or uncombined, are in constant motion.

The atomic motions of each element observe definite periods of time in their recurrence.

Atoms of different elements observe different periods of time in their movements.

These prefatory remarks prepare us to recognize our little microscopic cell as a complex molecular substance possessing energy, and that this energy or power to do work is the result, and represents the total motions, of its contained molecules. If it was possible to magnify one of these cells to a size sufficient to enable us to see its atoms and molecules, what a wonderful sight would be offered us! How astonishing it would be to witness the arrangement of its millions of molecules, and millions upon millions of atoms, all in constant motion, and, under the rule of nature's laws, working harmoniously together for the common good. But even if it was possible, through any device of science or art, to witness the molecular structure and movements of a cell, we would yet be only upon the threshold of our investigation, and would still have much to learn regarding the life-history of the cell.

If all the facts of cell-life were known, then life itself would cease to be a mystery. It would become as an open book, because a knowledge of cell-life carries with it a knowledge of animal and vegetable life, inasmuch as animals and vegetables are simply arrangements, more or less complex, of cells arranged and differentiated, in accordance with natural laws, to perform various functions of the organism. It may, then, be safely asserted that within the compass of a little microscopic cell is concealed the mystery of life, and it is not improbable that life itself had its first manifestation, on this planet, in cell structure. In matters of lineage, the cells are preeminently the oldest inhabitants of the world; almost from the beginning of time, certainly from the beginning of organized life, these little bodies have been fighting for existence, and perhaps, like more complex but less humble organisms, have struggled for a betterment of their condition.

I can see no reason why the laws of descent and heredity should not apply with the same force to cell-life that they do to organisms of complex cell-life. If this is true, and the development of unicellular organisms occur along the same lines, and is governed by the same laws which control the development of multicellular organisms, then, in the early history of cell-life, certain complex molecular substances, favored by the peculiar environmental causes which must have prevailed at the time, developed into a multiplicity and diversity of cells. The differences manifested by the innumerable varieties of cells thus created would depend upon the differences in their molecular arrangements, and would cause the different varieties to develop in different directions; those varieties which were found to be in the best harmony with their surroundings, best fixed in their molecular combinations, best able to successfully resist injurious influences, which perhaps would be fatal to the less favored sort, are the ones which would survive the struggle for existence and be selected by nature for propagation purposes. Now, as these selected varieties would transmit to their progeny their structural advantages, and from this progeny nature would again select the fittest, thus, in accordance with the laws of heredity and selection, there would be a progressive development of selected varieties from generation to generation, through the long period of time since cell-life first began. In harmony with, and as a result of, these laws of nature, cells and cellular organisms, in constantly adapting themselves to environmental causes, which themselves have been mutable and have been subject to the laws of progressive development, have passed from the simple to the complex, and from the undifferentiated to the differentiated cell-structures. Prominent among the environmental causes which determine the life and development of cells and cellular organisms are climate and cell-antagonisms.

Climatic influences are important factors in determining the geographical distribution of bacteria. For the same reason that every country has its own peculiar flora and fauna, it has also its indigenous bacteria. And as the flora and fauna may, by artificial means, be to some extent acclimated in foreign soil, so nature has provided that bacteria, when conveyed to foreign countries, may, under favorable atmospheric and climatic conditions, find in such countries conditions suitable for their growth and multiplication, at least for a time. In these facts are found an explanation of epidemic diseases which at times sweep over the country.

The subject of cell-antagonisms is receiving a great deal of attention from men of science. It is generally

conceded that these innocent-looking little bodies do not dwell together in peace—on the contrary, they are constantly warring upon each other. In this "battle of cells," which has been waged since the beginning of cell-life, the survivors have learned, or acquired through heredity, certain means of attack and defence. It can be readily seen why qualities thus acquired and transmitted by heredity would be more firmly fixed in the cells of complex organisms, thus giving such organisms important advantages over simpler ones in the battle of cells. It will be observed, however, as in the battles between men, so in the battles between cells, skill does not always succeed against numbers.

In the light furnished by these facts we will endeavor to explain in what manner, or by what method, the cell excites fermentation and causes decomposition of complex substances.

Picture in your mind's eye the marvellous mechanism of one of these little cells, with its contained molecules in active motion; remember the molecules are not in contact, but separated from each other by spaces which, although infinitely small to our comprehension, are really large when compared with the size of the molecules; remember, also, that the molecular movements are not of the hap-hazard sort, but are governed by fixed laws, and that while similarly constructed molecules have similar modes of motion, there are marked differences, in this respect, between molecules of dissimilar construction. As the molecule receives its motion from its constituent atoms, the cell must receive its energy from its constituent molecules. Remember that atomic and molecular motion constitute force, so that, when we speak of cell-motion we mean to imply cell-force, its power to do work, and the explanation which is offered will follow almost as an inevitable result.

The explanation of differences in cell activities is based upon the law that force, the efficient cause of all physical phenomena, is motion—atomic, molecular, or molar; that heat, light, electricity, attraction, and repulsion are simply modes of one and the same motion, which can be converted or changed from one into the other. Now, there is a marked difference in the kind of work which these different forces or modes of motion can do; for example, electricity can decompose many substances that light does not affect; on the other hand, light decomposes other substances over which electricity has no power; while heat, in its decomposing power, has a much larger range of action than either of the others.

The way or method by which these forces do this work, each of its own kind, can be better understood by means of an illustration. When a musical sound or note is made by any instrument, for example with a violin, in a room containing an open piano, the same note will be sounded by this instrument. Now, sound is a mode of vibratory motion, and in the example cited, when the string of the violin is vibrated so as to cause a musical note, this vibration is communicated to the surrounding air, and any musical instrument within reach of any of these sound-waves, if tuned in unison with them, will be thrown into vibration by them and produce the same note; the other strings or chords of the piano remain silent for the reason that they do not vibrate in unison with the note made by the violin; more correctly speaking, only that chord will vibrate whose period of vibration is equal to that of the string.

In the ears of all animals there is an arrangement of rods and hair-cells constituting what is known as the organ of Corti; this has been likened to a "harp of a thousand strings." I do not vouch for the supposed resemblance to a harp, but it at least can be asserted that the rods and hair-cells are arranged in such a manner that they can vibrate in unison with all vibrations whose period of time lies within certain limits. Some of the rods or hair-cells are tuned in unison with one note; that is, they vibrate in the same period of time, while others are vibrated by other notes. In every instance, however, the little rods and hair-cells take up the refrain, or are vibrated only by those sound-waves having the same period of vibratory recurrence.

Light is another mode of motion, and, like sound, has its waves, which differ among themselves in their periods of recurrence. The different colors of light are produced by the different wave-lengths. In the retinal coat of the eye there are little rods and cones which vibrate in harmony with the different wave-lengths of light; some are vibrated by one color and others by other colors. In every instance the vibrations of light must be in unison with that of the rod or cone before the color can be recognized.

When waves of light or heat or water meet other waves of the same substance, in such a manner that the crests of one set will correspond with the crests of the other set, and the troughs of one will correspond with the troughs of the other, the waves will be enlarged, increased in amplitude.

Now, it is assumed that different varieties or species of cells have molecular vibrations which, in their periods of recurrence, are distinctive of such species or variety; hence the molecular movements of cells are influenced in a certain way by other cells whose molecular periods of vibration coincide with those of the first in point of time. The wave-crest and trough from one cell striking the molecular waves of another cell less firmly fixed in its structure, crest to crest and trough to trough, the motions of the first would necessarily increase the swing of the second until the cell-molecules were swung beyond their attractions and the cell disrupted. The cell-molecules thus set free would recombine in accordance with chemical laws to form simpler compounds; for example, in the vinous fermentation the molecular combinations of the yeast-cell are so timed in their motions that they can swing the molecules of sugar, held in solution, beyond their chemical attractions, and thus cause a disruption of the sugar; at the same time the molecules or atoms thus liberated recombine to form a simpler compound, alcohol. Other cells cannot do this work, for the reason that their molecules do not vibrate in the required periods of time. In the same manner the micrococcus aceti decomposes alcohol into acetic acid, and other bacteria perform their special kinds of work and are incapable of doing the work of other varieties. In the same manner, pathogenic bacteria shake apart certain cellular albuminoid molecules in the blood or tissues of man and animals, while the recombination of molecules thus liberated form poisonous alkaloids called ptomaïnes and toxines, which are the immediate causes of the symptomatology and pathology of infectious diseases. The decomposition of albuminoid molecules by cell metabolism, principally bacteria-cells, and the influences which the products of this action, ptomaïnes and toxines, have in the causation of disease, is a subject of greatest importance to the physician.

The albuminoid molecules, from whatever source derived, present certain lines of separation, like the lines of cleavage in crystals, along which they are most easily disrupted or shaken apart by cell-vibrations; hence the character of the decomposition product depends along which of these lines separation has taken place. "At least three distinct series of chemical bodies are formed, viz., an acid series, an aromatic series, and a basic series. Out of the innumerable products arising from the action of bacterial cells upon albuminoid molecules, and which have been extracted and studied, will be mentioned indol, cresol, and skatol in the aromatic series, creatine in the basic, and uric acid in the acid series, serving only as mere examples" (*Journal of the American Medical Association*). "Cells other than those of bacteria are also capable of decomposing albuminoid molecules, and thus produce poisonous substances, *e.g.*, in the physiological changes from albumins to peptones there is a change from innocent to toxic bodies; this may be illustrated by the hypodermic injection of the digestive leucomaïne of fibrine by pepsin. It occurs practically when, after the

too hearty meal, the liver is unable to care for the excess of digestive leucomaïne, and they escape into the general circulation, producing somnolence, lassitude, or even stupor" (*Journal of the American Medical Association*).

On this subject Dr. Joseph Leconte says: "The leucomaïnes, although formed by normal physiological process, are highly poisonous and inimical to health, unless speedily eliminated by appropriate organs. If, now, there should be a failure to eliminate these toxic elements, the results would be similar to those produced by disease germs, except that they would lack the quality of contagiousness, because they are not due to the presence of microbes. The liver is the organ principally concerned in the elimination of leucomaïnes" (*Journal of the American Medical Association*).

"If alkaloids, by the conjugation of Sibiliary acids, if carbo-hydrates they escape the liver, and are taken care of by the blood and pancreas. If belonging to the class of phenols they are combined with a sulphuric radical, and when that gives out, are then combined with glycosuric acid and thus rendered innocuous" (*Journal of the American Medical Association*).

It is thus shown that fermentation may be the result of molecular motion, and that this process would take place whether the necessary vibrations originate in the yeast-cells, the bacteria-cells, or digestive ferments, which are the efficient cause of normal digestion. The principles involved in each case, the *modus operandi*, are the same in all. At this point, however, the similarity of results existing between bacteria ferments and digestive ferments ceases. There is an important difference in their biological history, which carries with it an important and practical distinction. I refer to the fact that bacteria and yeast-cells are living organisms, capable of multiplying themselves by the generative act, and hence, in the case of pathogenic bacteria, are capable of inducing contagious and infectious diseases. On the other hand, the digestive ferments are molecular combinations, which have no powers of self-multiplication, and cannot cause disease of an infectious or contagious character. There is a wise and beneficent law of wide application, the operation of which controls the course and duration of infectious fevers; this law is based upon the fact that the products of cell-decomposition are poisons which destroy the cells, or the fermentation, or infection which they excite. Thus alcohol is destructive to the yeast-cells and the vinous fermentation, while acetic acid, butyric acid, and lactic acid will arrest the fermentations of which they are the products, and, in the same manner, ptomaïnes and toxines arrest the infectious diseases of which they are severally the causes.

On this subject Dr. Klein says: "One of the most interesting facts observed in the growth of septic micro-organisms is this, that the products of the decomposition, started and maintained by them, have a most detrimental influence in themselves, inhibiting their powers of multiplication; in fact, after a certain amount of these products have accumulated, the organisms become arrested in their growth, and finally may be altogether killed."[1]

Pasteur says: "Many microbes seem to give rise during their breeding to substances having the property of being harmful to their own growth."[2]

It is evident that the periods of time in which occur the molecular vibrations of any given cell must swing in perfect unison with the vibrations of any other cell, or molecular structure, before the first can swing apart the molecules of the second. Crest must correspond to crest, and trough must correspond to trough, before the one set of vibrations can sufficiently increase the other to cause its disruption. When the arrangement is complete, *e.g.*, the vibrations of the bacteria-cell coincide in their periods of recurrence with the molecular vibrations of the albuminoid molecular substance, and decomposition of this results, thus liberating its constituent molecules.

[1] Micro-organisms and Disease.
[2] Comptes rendus, Academy of Sciences, October 26, 1885.

It is evident that no new compound can form from these molecules unless its periods of vibratory recurrence do not coincide in point of time with those of the bacterium cells; the same influence which disrupted the albuminoid molecules would prevent the forming of other compounds having the same periods of vibratory motion; in fact, they must be of an opposing kind in order not to be influenced by the bacteria-cells. Now, it is again evident that when a ptomaïne, possessing a molecular vibration which antagonizes that of the bacteria accumulates in a sufficient amount, the antagonism which it offers will be sufficient to arrest the motions of the bacteria-cells, and thus put a stop to the cell metabolism which they caused —in other words, to arrest the disease.

Perhaps this power, which waves or vibrations have of increasing or destroying similar waves or vibrations, may be better understood by reference to instances where waves of sounds and waves of light thus influence each other. Take, for example, two tuning-forks which have equal periods; when sounded each will give out the same continuous musical sound. Let us, however, change the vibrations in one of the instruments, by attaching some substance to it, or in any other way. The two instruments will no longer vibrate together, the vibrations will not coincide in time, hence the sound that will be given off by them will no longer be a continuous musical note gradually fading away, but will be a rising and falling sound. When the two instruments vibrate together, the sound will be distinct. As one vibrates more rapidly than the other, they will gradually part company, and the sounds which they give out will coincide less and less in point of time as one gains upon the other, and become fainter and fainter, and disappear when the wave crest of one coincides to the wave trough of the other. After passing the line, the sound becomes gradually more and more distinct until it again reaches its acme, when crest and trough coincide to crest and trough of the other side, and thus the sound will rise and fall, depending upon the amount of wave interference or antagonism, until the vibrations are exhausted.

It is thus seen that sound-waves can be caused to so act upon each other that, instead of producing sound, they will cause silence. Illustrations could be given, if it were necessary, to prove that when waves of light are met by other waves of light whose periods of vibrations are one-half wave length behind the first, darkness will be the result. The waves of the one set are quenched or antagonized by those of the other, in accordance with the law of wave-interference. This beautiful and important law was discovered by Dr. Thomas Young, one of the most remarkable men the world has produced. Speaking of this law, Sir John Herschel says: "This principle, regarded as a physical law, has hardly its equal for beauty, simplicity, and extent of application in the whole circle of science." The principles involved in this law of interference furnish an explanation why ptomaïnes are inhibitory, and sometimes poisonous, to the bacteria-cells which originated them. The amount of antagonism exerted by the ptomaïnes, in accordance with this theory, would depend entirely upon the extent of interference which its molecular waves would cause in the molecular waves of bacterium cells. As the amount of interference in waves of sound and waves of light varies, and thus produces variable amounts of sound from zero up, there are ptomaïnes whose inhibitory power over the actions of cells differs in the same degree and from similar causes.

Summary.—The explanation of the phenomena of contagion which our theory offers is based upon the application of the laws of wave-motion to the motions of complex organic molecules; thus, when waves of sound, of light, or of water meet other similar waves, the amplitudes of the resulting waves are increased; when, however, the waves are dissimilar, the amplitudes of the resulting waves are diminished. As a means of illustration we will apply these laws to waves of water. Now, a wave of water has certain dimensions, *e.g.*, it has a front, a back,

a crest, a trough, and has amplitude. The crest is the top, and the trough is the bottom of the wave, amplitude is the distance from the top of one to the top of the next (nearest) wave.

Now, when two bodies of water, approaching each other from opposite directions, meet, if the waves of each body coincide in the time of their upward and downward movements, the resulting waves will have their amplitudes enlarged, *i.e.*, the distance from crest to crest will be increased; if, however, the approaching waves do not coincide in time, should the crest of one set coincide with the trough of the other set, the amplitudes of the resulting waves will be diminished; or the downward force of one set of waves meeting the upward force of the other set, the result may be a complete antagonism of forces and the waves may be destroyed.

Assuming that the movements of complex organic molecules are also governed by these laws, it follows that, when molecular waves of one combination meet molecular waves of another combination, the waves of the first coinciding with those of the second, the amplitude will be increased in the waves of that substance which is the least firmly fixed in its structure; this increased amplitude means an increased distance between such waves, and when the distance is sufficiently great to remove the molecules beyond the limit of their attractions the combination becomes disrupted and the molecules liberated. It is well known that these liberated molecules cannot long remain in this free condition, they will be forced, by their mutual attractions, to recombine into combinations of simpler, and, for this reason, more fixed substances. It follows, as a result of these disrupting forces, that this new combination must have periods of molecular vibration that do not coincide with those of the disrupting cause. Hence the molecules of this new compound will interfere with the movements of the molecules of the other substance, and, when the interference is sufficient, will destroy them, just as interfering water-waves destroy other waves of water. In harmony with these facts we can understand how the molecular movements of a bacterium cell disrupt the molecular combination of albuminoids, and why the ptomaines, which result from the rearrangement of the liberated molecules, have the power of arresting or destroying through their interference the destructive forces of the cell.

Immunity: how Secured.—Immunity signifies a condition of body which opposes the development of infectious processes, or, more accurately stated, it is a condition of the body which opposes the invasion of bacteria. We will not stop to discuss the many theories—beautiful, ingenious, but incompetent—which have been suggested in explanation of how immunity is secured, but will proceed to show that an application of the laws of wave-motions to organic molecules, together with an application of the laws of descent to the evolution of cells, will furnish a complete explanation of all the known phenomena of immunity.

The physical and biological premises upon which this theory of immunity is built postulates the necessary existence of a natural law of immunity from bacterial influences, through the operation of which all organisms, both animal and vegetable, are to a large extent rendered immune from the action of bacteria-cells; the exceptions to the universal prevalence of this law constitute individual or racial susceptibility to infectious processes. Hence it becomes necessary to explain the causes of this natural law of immunity, and later, to indicate and explain the causes of its exceptions. That man and animal are, as a rule, exempt from bacterial invasions is evident; were it not for this law man would be destroyed by the hordes of microbes which surround him and which would attack him from all sides, which enter his body with the air he breathes, with the food he eats, and with the water he drinks. In the face of such a vast army of foes he would be absolutely helpless, if it were not for this natural law of immunity. It will perhaps be answered that the reason man escapes injury from this horde of bacteria is to be found in the fact that they are innocuous. This answer is only partially true, for while they may be innocuous to man, they are frequently virulent to other animals; besides, this answer does not carry with it an explanation of why they are innocuous to man. The answer to this inquiry will necessarily include an explanation of the natural law of immunity. An investigation into the working of this law discloses the fact that differences exist among different races of people, and, to a less extent, individuals of the same race, regarding the kind of immunity which this law secures to them; *e.g.*, it is established that certain races are largely immune from yellow fever, and other races from syphilis, while individuals of these several races possess different degrees of susceptibility to these influences. Admitting that this racial, and, to a less extent, individual, immunity may in part result from long exposure to the infecting causes, the principal cause, it must be conceded, rests upon structural differences between the races. In a series of articles published in *The Lancet* in 1888, upon the pathology of infectious and infective diseases, Dr. Joseph Coates, the eminent pathologist, in discussing the causes of natural immunity, uses the following language in the summing up of his conclusions: "We have seen that, in the case of a large number of diseases of this class, inheritance, whether we take it more broadly in the race, or more particularly in the family, has an undoubted, and frequently a very great, influence on the susceptibility to infection. This varying degree of susceptibility exists in the cases of diseases which are demonstrably due to a micro-organism which is pathogenic in the individuals of one race to a high degree, and is non-pathogenic, or nearly so, in individuals of another race. Recurring to our remarks on the general principles of inheritance, it seems necessary to refer this difference in susceptibility to fine differences in the structure and activity of the tissues. We have seen that the differences in the races depend on variation in the details of their tissues." There are two theories of immunity before the world for a verdict, to which we must devote some attention. The theory of phagocytosis ascribes to certain cell-elements, *e.g.*, the white blood-cells, connective-tissue cells, endothelial cells, and cells of spleen, bone, marrow, and lymph-glands, which are generically called phagocytes, the property of attacking and devouring bacteria. It is said they cannot devour the pathogenic forms until they have been put through a system of training with the attenuated ones. Metchnikoff is the founder and leading advocate for this theory; other eminent bacteriologists, however, have verified the work done by Metchnikoff, and are equally zealous with himself in asserting the truth of the theory. The second theory ascribes to the normal tissue-fluids of the body a germicidal action. This theory is based upon carefully conducted experiments by Nutal, Buchner, Labarsch, and Prudden with blood serum and other tissue-fluids, associated with and also separated from their cellular elements; and, it is claimed, proves that these fluids, and not the cells they contain, are highly germicidal to many, but not to all, bacteria. While one theory seems to oppose the other, in so far as one ascribes the germicidal action to the cell-elements and the other to tissue-fluids and blood serum, although deprived of cells, this opposition in fact does not exist; for it is more than probable that both cells and fluids of the body are germicidal; at the same time the germicidal powers may greatly differ in important respects. While the fluids may be competent to destroy some varieties of bacteria, they may be incompetent to injure the other varieties, or the cells may be competent to resist bacteria that are inimical to the fluids. The following quotations from Dr. Prudden's article "On the Germicidal Action of Blood Serum and Other Body Fluids," may be heard with interest:

"To account for the disappearance of pathogenic bacteria in the body, either in the course of an acute infectious disease, or as the result of exposures which we may sustain unharmed, several more or less plausible theories have been evolved.

"That one of these which has attracted most attention, partly because it has been most ably advocated, and partly because it lends itself most readily to experimental observation, is that called the theory of phagocytosis. This theory is too well known to require detailed exposition here; suffice it to say that it postulates the taking up into their bodies and the destruction there of living micro-organisms by certain lowly organized cells, especially the leucocytes. A large amount of very plausible experimental evidence has been adduced in favor of this theory, and a good deal of this evidence has been unconditionally accepted by medical men. Metchnikoff, the chief expounder of this theory, claims that this destruction of the life of the bacteria by being taken into the bodies of certain cells, phagocytes, is the exclusive means which the organism makes use of in resisting the incursions of pathogenic bacteria. An animal whose leucocytes can successfully battle with and eat up a given species of bacteria, according to this theory, enjoys immunity from its deleterious effects.

"But the doctrine of phagocytosis, at least in the scope which is claimed for it, appears to most unprejudiced observers less and less to commend itself the more facts and observations on which it is based are critically examined and judiciously interpreted.

"The series of observations on which this theory largely rests, varied and elaborated in many ways, indisputably teach this, that when micro-organisms are introduced into the body, either naturally or artificially, the phagocytes which gather round them may be found after a time to have taken more or less of the germs into their bodies, where they show the morphological evidences of degeneration, which indicate that they are dead. That this phenomenon does occur is well enough established, but that it should be interpreted as necessarily meaning that the micro-organisms are taken in the living condition into the bodies of the cells, and are there deprived of life, appears to be very doubtful indeed." This quotation is sufficient to indicate that phagocytosis, like the Scotch verdict, is not proven.

Let us now learn what Dr. Prudden has to say, in the same article, regarding the germicidal properties of blood serum and other tissue-fluids. We will quote from his summary, and the concluding remarks of the article referred to.

"It will thus appear, as to the general result of all this recent work, that, first, blood serum possesses, though in different degrees in different animals, and in varying potency with the different bacterial species, a most marked germicidal power; that a similar germicidal power resides in fresh human non-inflammatory transudations. That this power is not directly associated with the formed elements of the blood or the transudates, but is in some way dependent upon their albuminoid constituents. It would further appear that this singular, and, apparently, most significant capacity of the body fluids, is intimately associated with the complex condition which we call life."

"The significance of these new discoveries would seem to be very great and far-reaching, and not only in explaining many obscure phenomena of the acute infectious diseases and in their bearing upon the doctrine of immunity, but also in calling back the attention of therapeutical adventurers from germicidal warfare with certain forms of infectious diseases, to what appears to be a natural defence of the organism against bacterial invaders, namely, a healthy condition of the blood." . . .

"But our knowledge of this subject is too fragmentary and too little digested to permit us to do more at present than follow the general indications of its lead. . . .

"The fact that one of the most abundant of the pathogenic bacteria, the staphylococcus pyogenes aureus, appears to be quite invulnerable to this destructive agency, would indicate the necessity of cautious inferences. . .

"It is a little humiliating, though doubtless salutary, to find ourselves face to face with a series of phenomena which seem to lie at the very basis of the knowledge of acute infectious diseases, and yet able to say only that they are the result of the vital forces."

These quotations from Prudden's paper furnish us the salient features of the two theories of immunity, some of the objections which are urged against them, and evidence of their incompetency to explain all, or even a large part, of the phenomena of immunity; they also give us an idea of the character and extent of known phenomena of natural immunity, which must be rationally explained by any theory before its truth can be accepted.

The chief difficulties, as I conceive them, which stand in the way of a correct knowledge of the laws of natural immunity are found in the obscure vitalistic conceptions entertained regarding the structure and activities of tissue, and the laws of inheritance in their application to the evolution of cell-development. We will endeavor to show that structure is an arrangement of molecules in cells, and that differences of structure consist in differences of molecular combinations with their associated movements in definite periods of time; and that these varying forms of molecular aggregation, whether found in cells, in protoplasm, or in albuminoids, have resulted from the operation of the laws of natural selection, heredity, and adaptation. These views will no doubt appear to many persons quite startling, as do all declarations which seriously disturb the usual order or prevailing opinions of men. It can hardly be claimed, however, that they are untenable; on the contrary, they are based upon accepted physical laws, and explain many phenomena which cannot otherwise be explained, whether these are observed from the stand-point of the physiologist, the biologist, the physicist, or the chemist. The warrant for making this statement is found in the writings of Michael Foster, Professor Huxley, Professor J. Clerk Maxwell, and Julius Thomson; it is needless to say that the opinions of such men, in matters relating to their special departments of science, are entitled to the greatest respect. Professor Michael Foster, M.D., says: "We have, in speaking of protoplasm, used the words 'construction, composition, decomposition,' and the like, as if protoplasm were a chemical substance. And it is a chemical substance in the sense that it arises out of the union or coincidence of certain factors which can be resolved into what the chemists call 'elements,' and can be at any time, by applying appropriate means, broken up into the same factors, and indeed into chemical elements.

"This is not the place to enter into a discussion of the nature of the so-called chemical substances, or, what is the same thing, a discussion concerning the nature of matter; but we may venture to assert that the more these molecular problems of physiology, with which we are now dealing, are studied, the stronger becomes the conviction that the consideration of what we call 'structure' and 'composition' must, in harmony with the modern teachings of physics, be approached under the dominant conception of modes of motion.

"The physicists have been led to consider the qualities of things as expressions of internal movements; even more imperative does it seem to us that the biologist should regard the qualities (including structure and composition) of protoplasm as in like manner the expression of internal movements.

"He may speak of protoplasm as a complex substance, but he must strive to realize that what he means by that is a complex whirl, an intricate dance, of which what he calls chemical composition, histological structure, and gross configuration, are, so to speak, the figures; to him the renewal of the protoplasm is but a continuance of the dance, its functions and actions the transferences of figures." . . . "And the conception which we are urging now is one which carries an analogous idea into the study of all of the molecular phenomena of the body."

"We must not pursue the subject any further here, but we felt it necessary to introduce the caution concerning the word 'substance,' and we may repeat the assertion that it seems to us necessary, for a satisfactory study of the

problems on which we have been dwelling for the last few pages, to keep clearly before the mind the conception that the phenomena in question are the result, not of properties of kinds of matter, in the vulgar sense of these words, but of kinds of motion." [1]

Professor Huxley says: "The broad distinctions which, as a matter of fact, exist between every known form of living substance and every other component of the material world, justify the separation of the biological sciences from all others. But it must not be supposed that the differences between living and not living matter are such as to justify the assumption that the forces at work in the one are different from those to be met with in the other. Considered apart from the phenomena of consciousness, the phenomena of life are all dependent upon the working of the same physical and chemical forces as those which are active in the rest of the world."

"It may be convenient to use the terms 'vitality' and 'vital force' to denote causes of certain great groups of natural operations, as we employ the names 'electricity' and 'electrical force' to denote others; but it ceases to be proper to do so, if such a name implies the absurd assumption that 'electricity' and 'vitality' are entities playing the part of efficient causes of electrical or vital phenomena."

"A mass of living protoplasm is simply a molecular machine of great complexity, the total results of the working of which, or its vital phenomena, depend on the one hand upon its construction, and on the other, upon the energy supplied to it; and to speak of 'vitality' as anything but the name of a series of operations is as if one should talk of the horology of a clock." [2]

Professor J. Clerk Maxwell says: "Thus molecular science sets us face to face with physiological theories. It forbids the physiologist from imagining that structural details of infinitely small dimensions can furnish an explanation of the infinite variety which exists in the properties and functions of the most minute organisms."

"A microscopic germ is, we know, capable of development into a highly organized animal. Another germ, equally microscopic, becomes, when developed, an animal of a totally different kind. Do all the differences, infinite in number, which distinguish the one animal from the other, arise from some difference in the structure of the germs? Even if we admit this as possible, we shall be called upon by the advocates of pangenesis to admit still greater marvels. For the microscopic germ, according to this theory, is no mere individual, but a representative body, containing members collected from every rank of the long-drawn ramification of the ancestral tree, the number of these members being amply sufficient to furnish not only the hereditary characteristics of every organ of the body and every habit of the animal from birth to death, but also to furnish a stock of latent gemmules to be passed on in an inactive state from germ to germ, till at last the ancestral peculiarity which it represents is revived in some remote descendant." [3]

Julius Thomson, in his introduction to "Thermochemical Investigations," says: "Theoretical chemistry is based upon the molecular theory, according to which all matter is made up of molecules, and these molecules of atoms. The physical state of bodies depends upon the arrangement and motions of the molecules, the other physical and chemical properties depend upon the kind and number of atoms in the molecule, upon their arrangement and relative motions." [4]

In a former part of this article we endeavored to explain that certain cells would be virulent to other cells when the first were able to disrupt the molecular combinations of the second, and that this power of disruption was exercised by the more stable molecular combinations, whose periods of molecular vibrations coincided with the less stabile in periods of recurrence. Under these conditions the cells of virulent bacteria, with their contained molecules vibrating in definite periods of time, would shake apart the molecules of other cells or molecular combinations, *e.g.*, the albuminoid molecules of the cell-elements or fluids of the blood or tissues of man, provided these vibrated in periods of time coinciding with those of the bacteria cells; for the reason that the first are more fixed in their molecular combinations than the second, and consequently are better able to withstand the increased kinetic energy manifested by an increase of wave amplitude, which molecular waves, rapidly superposed on other molecular waves of the same periods of recurrence, would necessarily induce.

Bacteria cells whose wave-lengths do not coincide in periods of recurrence with those of any cells, blood serum, or tissue fluids of man, would for this reason be innocuous to man. At the same time they might find, in fluids or tissues of other animals, molecular combinations which these bacteria could disrupt, and for this reason they would be virulent to such animals.

I presume that no one will deny that cell structure, or that of the normal tissue fluids of man's body, varies in many respects, and that these variations correspond to the ultimate use of such fluids in supplying the different cells of the body with the means of repair and regeneration. Admitting this proposition, it follows that different cells and different fluids of man's body, notwithstanding their macroscopic or even microscopic similarity of appearances, possess molecular combinations differing among themselves, and peculiar to each class or variety, and consequently cannot be affected alike, or at all, by the same bacteria; some bacteria would find vulnerable structures in the blood and other fluids of the body, others in the fixed cells, and others perhaps in the contents of the alimentary canals. Some would be virulent to man and innocuous to animals, others would be virulent to some animals and innocuous to others, and would thus present many differences of action—which in fact are found to exist in nature.

Cell structure is thus resolved into molecular combinations, while cell immunity is the result of molecular vibrations. Hence it follows that the law of natural immunity depends not alone upon inherited qualities acquired by man as a complex cellular organism, but also upon qualities which each individual cell or molecular combination has acquired for itself through the operation of the laws of inheritance and adaptation

We have already endeavored to outline the results that would be obtained by the application of the laws of natural selection, heredity, and adaptation to the evolution of cell life.

In an infinite number of created cells there would exist infinite differences in their molecular combinations, which would determine species and varieties, and would also determine the lines of development which the different species and varieties would pursue, as well as the extent of development which the species and varieties could attain. Thus, in consequence of this molecular structure, some cells would find their fixed point of development in unicellular organisms, while others would enter into and assist in the formation of complex multicellular organisms. All cells from the beginning, in consequence of the differences in their molecular combinations causing equal differences in their molecular vibrations, would wage incessant war upon each other because of the actions, interactions, and reactions of their molecular vibrations, until there would eventually result an adjustment of their forces, through the operation of the laws of natural selection, heredity, and adaptation, resulting, to a great extent, in their individual and special immunity. By natural selection we mean that law of nature whereby she selects from a large number of organisms those varieties and species which are in best harmony with their environment. By heredity we understand that natural law which transmits through the race those qualities, possessed by varieties or species, which determine their selection by

[1] Encyclopædia Britannica, 9th ed., Article Physiology.

[4] W. R. Nichols: Popular Science Monthly, October, 1883.

nature. By adaptation we understand that law which enables organisms, during their generation, to adjust themselves to their surroundings; qualities thus acquired may be, to a limited extent in long periods of time, transmitted through inheritance. Environment constitutes those natural causes, *e.g.*, climate, food supply, temperature, moisture, etc., which determine the species or varieties which nature will select for the purpose of propagating the kind.

No correct opinion of cell life or the life of cellular organisms can be had. There can be no correct conception of the causes of cell immunity, whether it be a bacterium cell or one found in man's body, or, for that matter, found in the cells composing his entire body, that is not based upon the evolution of cell life, through the laws of descent from the simple to the complex, and from the undifferentiated to the differentiated cell structure. It is in this manner and in conformity with these laws, that man has acquired his natural immunity from bacterial invasions. The molecular vibrations natural to the various cells and fluids of his body render him immune to a great extent from what might be otherwise fatal influences. Now, these molecular cell combinations and their equivalent molecular vibrations are qualities of inheritance, and represent certain adjustments of molecular force gradually acquired by the ancient ancestors of these cells through wars and battles of cells, the like of which has never occurred in the history of man.

Having thus explained the causes which produced the laws of natural immunity, it would be proper to inquire into the reasons why this law is not absolute in its operations; why man is not immune from all infective and infectious diseases. To enter into this discussion and explain how the laws of natural selection, heredity, and adaptation are equally as competent to explain these exceptions to the law as they are to explain the law itself, would make this already lengthy paper too long to be read on this occasion. I have concluded to pass this portion of our subject, and devote the remainder of this paper to an explanation of the principles involved in artificially acquired immunity. It is well known that immunity from many acute infectious diseases can be secured by artificial means, *e.g.*, one attack often renders the individual immune from future attacks of the same malady. Another artificial means of securing immunity is to be found in what is termed "protective inoculations;" this method consists in the inoculation of an "attenuated" or weakened form of the virulent microbe which is the etiological factor in producing the disease. Thus anthrax, chicken cholera, small-pox, swine plague, and other forms of infectious disease are non-infectious to individuals who have been previously inoculated with the attenuated microbes of that disease from which they seek immunity. "Attenuation" of bacteria is produced differently with different varieties of pathogenic bacteria, and when once accomplished is more or less fixed as a condition of such bacteria. To all appearances they are the same, but are no longer able to decompose molecular substances, provided the attenuation is perfect; there are, however, degrees of this condition, so that the decomposing power of the bacterium will depend upon the extent of its attenuation, *i.e.*, at what point or stage the process of attenuation is arrested; thus the power of the cell to do its specific work is proportional to the extent of its attenuation. While the attenuated bacterium is usually fixed in this condition, at least to a very considerable extent, and will transmit this quality to its offspring through many generations, it can, by a reversal of the methods of attenuation, be brought back to its original condition of virulency. You will, perhaps, be reminded of the similarity of behavior in this respect between the bacterium and the yeast-cells. Oscar Brefeld, you will remember, succeeded, by a peculiar artifice, in modifying these cells in such a way that they would grow and multiply themselves in a solution of malt without producing alcohol.

The third and last means by which immunity against an infectious disease can be secured, is by previously injecting its characteristic ptomaïnes into the individual, beginning with small amounts and gradually increasing the dose as the individual becomes accustomed to the poison. This means of immunity, by the injection of specific ptomaïnes, is of recent discovery, and bids fair to become of great practical advantage. It already explains what had been previously very obscure, how the pregnant mother gives immunity, for example, in syphilis, to the child in utero.

It is generally admitted that solid particles, like bacteria-cells, cannot pass from the mother through the placenta to her child in a normal state of the placental tissues; hence, the fact of the child's immunity secured through the mother was not understood. That soluble substances like ptomaïnes can pass in this way by osmosis is not questioned, and in doing so explains how the child receives from the mother immunity from syphilis and other infectious diseases.

These different means of securing immunity from certain infectious diseases, *e.g.*, immunity secured by a previous attack, immunity secured by protective inoculations with the attenuated bacterium, or with the specific ptomaïne, appear to be of a very dissimilar character, and cannot be harmonized by any of the theories at present offered in explanation of these processes. It will be observed, however, that when the principles involved in our molecular cell theory are applied to the elucidation of this problem, a striking similarity of action between these methods is seen to exist, and order is established out of chaos.

I will first invite your attention to the methods of securing immunity by inoculating attenuated bacteria and by inoculating the specific ptomaïnes, and show that practically the two methods are the same. We have previously explained how the pathogenic bacterium cell, through its molecular vibration, has the power of disrupting the albuminoid molecules which it finds in the blood or tissue fluids of man's body, provided that the molecules of this substance vibrate in the same periods of time, crest to crest and trough to trough, in which recur the molecular vibrations of the bacterium cell. This is an important principle which I hope you will fix in your minds. When two or more molecular combinations—for illustration, two cells whose molecules vibrate in the same period of recurrence—meet in the blood, or any other nutritive solution where the molecular activities have full play, that cell which is most fixed in its molecular combinations will shake apart the molecules of the other cells, drive them beyond their attractions, and thus disrupt the cell. When this conflict is between the molecules of bacteria-cells and combinations of albuminoid substances, and the battle-ground is the tissue fluids of man's body, the albuminoid molecules will be driven beyond their attractions and the combinations disrupted, for the reason, first, that they vibrated in unison with those of the bacterium-cell, and second, that they are less fixed in their combination than those of the bacterium cell. Now, when this pathogenic bacterium cell is attenuated, weakened in its power of disrupting the albuminoid molecules, it will produce only small quantities of ptomaïne; the amount of ptomaïne produced will depend upon the amount of attenuation the cell has received. So that, using these attenuated bacteria as the matter of inoculation amounts to the same thing as using small quantities of ptomaïne as the matter for such inoculations; the results obtained and principles involved are the same in either case.

How does one attack of an acute infectious disease give man immunity from other attacks of the same malady? is the question that now offers itself for our solution.

A bacterium cell disrupts molecular combinations of the albuminoids when the molecules of each vibrate in the same periods of recurrence; the albuminoid molecules which are thus disrupted or shaken apart, and liberated from their former combinations, will again immediately recombine, because of their attractive affinities, to form

other combinations which are called ptomaïnes. Explanation has been made why these ptomaïnes must of necessity have molecular vibrations which recur in periods of time that interfere with those of the bacterium cell, and when the ptomaïne accumulates in sufficient amount will, through the action of the law of interference, which applies to all wave-motion, so antagonize the bacterium-cell that its action will be destroyed, and it will no longer be able to disrupt the albuminoid combination. It is in this way, you will remember, that the yeast-cells are affected by alcohol, their ptomaïne, and it is this law of interference which explains why waves of light, or waves of sound, if they recur in different periods of time, may in the one case produce darkness, and in the other produce silence. You will observe that the reason the molecular vibrations of the ptomaïne thus interfere with those of the bacterium-cell, is due to differences which exist in the vibratory recurrence of the two substances, and that molecular vibrations, like the vibrations of light and sound, are subject to that beautiful and far-reaching law of interference.

Now, as the molecular vibrations of the bacterium cell coincide in all respects with those of the albuminoid combinations which it is capable of disrupting, it follows that the respective ptomaïnes will affect or interfere with the two substances alike, *i.e.*, the molecular vibrations of two substances being the same, any third substance whose molecular vibrations would interfere with those of one substance, would also interfere with those of the other.

Hence the ptomaïne which interferes with the bacteria cells will, for the same reason, interfere with certain albuminoid molecules. You will understand that this interference, exerted by the ptomaïne over the albuminoids, will change the molecular vibrations of this substance, that is, will change its molecular combinations, and as long as this interference, or this changed molecular combination, continues, such molecules could no longer be influenced by the bacterium cell, and the individual would be immune from that acute infection to which such bacteria stand in the relation of etiological factors.

Ptomaïnes are chemical substances, and like other chemical substances, do not find in man's body a permanent abiding-place, but are disposed of or eliminated from the body in a reasonably short time. How, then, are we to explain the more or less permanent immunity which observations and experience teach us is secured by the various artificial means which have been referred to?

The phenomena of interference, manifested in waves of light or waves of sound, continue only during the time that the interfering cause is in operation. You will observe that this rule does not apply to the interference between the ptomaïnes and albuminoids. How, then, are we to explain the fact that the phenomena of interference, manifested as change of molecular movements in the albuminoids of the blood, continue to persist more or less permanently after the cause of interference, the ptomaïne, has been removed or is no longer a cause of molecular interference. To fully understand this problem it is necessary to consider the nature of the two substances involved, the ptomaïnes and the albuminoids. The ptomaïne, a product of the disintegration of the albuminoid, is a less complex and more fixed substance than the albuminoid from which it is derived. The ptomaïne which will be produced in any given case is determined by the molecular structure of the active causes, the bacteria-cells, and the molecular structure of the substance acted upon, the albuminoids; as there are many varieties of the pathogenic bacteria and many differences in the molecular combinations of the albuminoids, there must result many different kinds of ptomaïnes. The albuminoids are of course derived from the food we eat, animal or vegetable. The molecular combinations which these substances had before entering our bodies, became greatly changed by heat in the process of cooking them, and further changed by the process of digestion to which they are subjected. As we find them in the blood or tissue fluids of man, they are plastic molecular compounds, well suited to furnish to the many different kinds of cells of which man's body is composed matter for their repair or regeneration. It follows that substances pressing such mobile molecular combinations of various kinds would be easily influenced by interfering bodies, and that the new molecular arrangements involved in this process of interference would be more or less permanent, and capable of being transmitted by the act of generation. That this is not an improbable assumption, but, on the contrary, a correct principle, is evidenced by the fact that changes of like nature in the molecular arrangements of cell structure, a much more fixed substance than the albuminoids, do occur from artificial causes, and that such new molecular arrangements become permanent and are transmitted through the act of generation. I refer to those changes produced in the pathogenic bacterium by the process of attenuation.

Immunity will then be more or less permanent, depending upon the degree of permanency in the molecular combinations of the albuminoids which the ptomaïne has imposed upon them. As a matter of fact infectious diseases differ very greatly, regarding the duration of immunity, if any, which one attack secures to the individual against other attacks. The phenomena, you will observe, in this instance as well as in all others, are in harmony with and capable of being rationally explained by our theory. So far as I know, there is no attempt to harmonize an explanation of these phenomena with the theory of "enzymes" or, for that matter, with any other theory. The atomic theory is accepted, and, in fact, is the foundation upon which is built the beautiful and stately structure, Chemical Science, although no man has ever seen an atom, and for that matter, will never see one; yet it is accepted because it is capable of explaining chemical laws and the phenomena of chemical changes. It can also be said of the undulatory or wave theory of light, the waves are invisible and likely to remain so, but the theory is accepted because of its competency to explain the phenomena and laws of light. And, if you will excuse the apparent egoism involved in making these comparisons, it is because the molecular cell theory is competent to explain the phenomena and laws of infection and infectious diseases, that I am convinced of its truth.

It will, however, do more than this. I am convinced that a right application of the laws involved in this theory is competent to explain many other dark problems of medicine—for example, that obscure subject involved in the power and potency of drugs and their therapeutical uses; and I predict that it will be along these lines of investigation that knowledge is to be obtained and progress made.

AUSTIN, TEXAS, March 7, 1890.

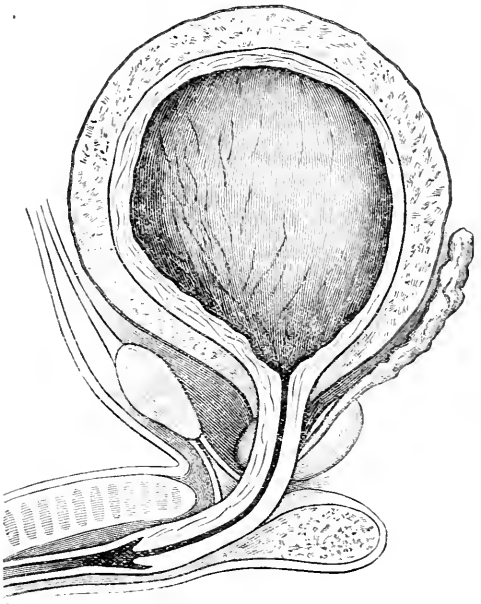
CONGENITAL MALFORMATION OF THE MALE URETHRA.[1]

BY ALEXANDER W. STEIN, M.D.,
NEW YORK.

OF the various congenital malformations of the male urethra that have been met with and recorded, this one is, as far as my reading goes, unique. It consists of an abrupt diminution of the canal, about an inch anterior to the membranous portion. The urethra is of normal calibre (33 F.) in front of the diaphragmatic obstruction. But here the mucous membrane is folded upon itself toward the lumen of the canal, and the urethra is reduced to about 15 mm. in circumference, and remains uniformly diminished to the vesical orifice, a distance of about three inches. It is given not alone for its teratological interest, but because of valuable suggestions which it presents to the practical surgeon. It is not necessary to dwell upon them, as they are too apparent, but I will

[1] Read before the American Genito-Urinary Association, June, 1890.

mention one of the difficulties which was experienced in this case. Because of the frequent micturition and the account he gave of himself of having had gonorrhœa, etc., a stricture was suspected. His urethra was thereupon explored, first the urethrotome, then the bougie à boule, and subsequently smaller instruments were passed. All met with a decided obstruction at about five inches from the meatus, giving the impression that a very narrow stricture existed. In consequence of the great difficulty of introducing instruments, after repeated trials, internal operations were abandoned, and external perineal urethrotomy without a guide was contemplated, as the only means of affording relief. But, had this operation been undertaken, the difficulties in the way of its performance can well be imagined. He was suffering from phthisis pulmonalis and was very feeble, and operative interference was deferred until he should become stronger. Treatment was directed to this end, but without avail. He died from asthenia in a few days. In the curator's book the following brief statement appears over the signature of one of the curators of the hospital: "F. H ——,



aged twenty-five; lungs, both upper lobes filled with caseous, tubercular material; kidneys, four ounces, capsule adherent; bladder hypertrophied; slight vascular engorgement of base; urethra exhibited a fold about three inches (?) from the meatus. The specimen was given to Dr. S——, for further study."

With the view of making the specimen more intelligible it was thought best to make a schematic drawing of it, rather than present it as it now exists, with the urethra laid open upon the dorsum of the penis as far as the narrowing. But it is essentially true to nature as represented

Inasmuch as the narrowing of the urethra had its origin at the vesical orifice, the canal is not dilated in any part of its course. There is a certain anatomico-physiological interdependence between the urethra and the bladder, or in other words, when the calibre of the urethra is diminished, either from an acquired or a congenital defect, an extra demand is made upon the functional activity of the bladder, and in consequence thereof its cavity becomes more and more diminished with the increasing obstruction or with the lapse of time. This is apparent in the specimen of the bladder before us, which, in the absence of further history, speaks for itself. It shows the additional strain with which it was encumbered for years, in the concentric hypertrophy of its walls, until its cavity was diminished to a capacity of not more than about two ounces. It might be said that in stricture, the deeper the coarctation—that is, the nearer it is to the bladder, the greater the probability, all other factors being equal, of distention and dilatation of the viscus. In stricture of the penile urethra, the canal suffers dilatation posterior to the contraction, in consequence of repeated hydrostatic pressure; but, while the integrity of the urethra is thus impaired, the stricture permits the urine to escape without diminishing the expulsive power of the bladder, unless retention succeeds. In vesical obstruction there is always a marked tendency toward the reverse of what we observe in strictures, high tension, atony and sacculation, or else to the non-inflammatory there is superadded an inflammatory thickening, with infiltration and organization of the submucous coat, rendering the bladder inflexible and indurated, unable to obliterate its cavity. These sequelæ are characteristic of prolonged vesical obstruction. In this case of urethral insufficiency, the embarrassment from which the man suffered for twenty-five years did not leave behind it any pathological manifestation.

ON GONORRHOIC IRIDO-CHOROIDITIS.[1]

By CHARLES J. KIPP, M.D.,

NEWARK, N. J.

It is not my intention, on this occasion, to review all that has been written on this subject, but simply to state what I have learned of this disease from personal observation. Judging from the number of cases I have had under my care, gonorrhœa is not a frequent cause of inflammation of the uveal tract. In only one-sixth of the cases of iritis from all causes seen by me in private practice, was gonorrhœa or gonorrhœal rheumatism present at the onset of the iritis, and in several of the cases in which the joint affection preceded the iritis it was even doubtful whether this was the result of gonorrhœa, as one or several slight attacks of rheumatism had occurred previous to gonorrhœa. According to some writers,[2] iritis never follows an inflammation of the urethra without some joint having been attacked previously, but this is not my experience, and Mackenzie,[3] Ricord, and others have also seen iritis follow gonorrhœa in patients free from rheumatism. I have seen four cases in which a violent inflammation of the uveal tract developed while the patient still had a specific urethral discharge, but no disease of any joint, and who had never had rheumatism. Whether or not the gonorrhœa was responsible for the eye disease in these cases I cannot say, but it seems to me that if, as is commonly assumed, the joint affection is the result of a diffusion of the gonorrhœal poison (probably gonococci) through the system by means of the circulation—a kind of metastasis of the virus—this can also cause an inflammation of the uveal tract. Gonococci have been found, according to Michel,[4] in the joints in cases of gonorrhœal rheumatism, but, so far as I know, no one has thus far found them in the interior of the eye in gonorrhoic iridochoroiditis. In the four cases seen by me no other disease than gonorrhœa was present at the onset of the eye disease, none had had syphilis, but in one an attack of rheumatism or gout had occurred four years before the gonorrhœa was contracted. In all of these cases the inflammation of the uveal tract set in three or four weeks after the beginning of the urethral discharge. As to the character of the irido-choroiditis observed in these cases, I may say that it did not differ from that seen in the cases in which joint disease preceded the eye disease, which

[1] Read by invitation before the Section of Ophthalmology, New York Academy of Medicine, February 17, 1890.

[4] Lehrbuch der Augenheilkunde, 1884, p. 471.

will be described further on. All these cases occurred in men.[1]

Passing on, now, to the irido-choroiditis following gonorrhœal rheumatism, I may state that my observations are based only on cases occurring in men. I have seen, also, the same eye affection after joint disease closely resembling gonorrhœal rheumatism in women, but as I was unable to ascertain whether the vaginal discharge from which they had suffered was of a specific character or not, I have not counted them among the cases of gonorrhoic iritis. Among the cases occurring in men there were, as I have already stated, a few in which a careful inquiry into their previous history revealed the fact that they had suffered somewhat from rheumatism previous to the appearance of the gonorrhœa. Whether in these cases the gonorrhœa stood really in a causative relation to the joint affection from which they suffered subsequently to the contraction of the gonorrhœa may be doubted, though, as a rule, a discharge from the urethra, with or without a new infection, preceded the attack of rheumatism afterward. The joints mostly affected in my cases were the knees, the hips, the ankles, and the elbows.

In some of my cases the irido-choroiditis occurred shortly after the initial attack of articular inflammation, while in others the eye disease did not develop till the patient had had several attacks of the rheumatism.

The articular inflammation in most cases came on three or four weeks after the appearance of the urethral discharge, but in one of my cases it developed as early as the fifth day, and in a few others not till the discharge from the urethra had entirely ceased.

As to the nature of the joint affection I can say but little from personal observation, as in nearly all the cases that came to me for the eye-trouble the joint disease had subsided for the time. In those that I saw while the joint disease was still active, I found several times the knee-joint enlarged from effusion in its capsule, and painful on motion; once I saw the hip-joint inflamed, and once I found the metatarso-phalangeal joint of the great toe red, shining, and enlarged, just as in an attack of gout.

Proceeding now to describe the eye affection, I may state that in only a very few of my cases was the inflammation limited to the iris and of a mild type. In all the others the disease presented itself under the form of an intense inflammation of the entire uveal tract with an abundant fibrinous exudation in the anterior chamber and an effusion in the vitreous body. In these cases there was found about the fourth day from the beginning of the disease, instead of the ciliary injection seen in simple iritis, marked chemosis and an intense congestion of the vessels of the whole ocular conjunctiva. The aqueous was usually from the beginning of the disease more or less turbid, and about the third or fourth day a yellowish gray exudation, not unlike a layer of wax, was found to cover the pupillary area of the anterior capsule of the lens; in several cases I found at the same time the lower half or the lower two thirds of the surface of the iris covered by a whitish granular deposit. During the following days there was usually a marked increase in the turbidity of the aqueous, so that the iris was only indistinctly visible, and this was followed soon by the appearance of yellowish white flakes in the aqueous or by the coagulation of the exudation into a gelatinous or spongy mass which sometimes nearly filled the anterior chamber. The iris was in all cases much swollen, and the pupil could not be kept in a state of dilatation by the frequent instillation of strong solutions of atropine and cocaine, even in cases in which these drugs were used from the very commencement of the disease. No ophthalmoscopic examination could of course be made at this stage. The sight was always greatly impaired. Intense pain in and around the eye was a marked feature in these cases from the beginning, and it usually continued till coagulation of the exudation in the anterior chamber had taken place.

[1] For a full report of one of the severest of these cases, see THE MEDICAL RECORD, January 26, 1880.

In some of the cases the coagula looked at first like an opaque lens suspended in the aqueous in front of the pupil; subsequently it was changed by absorption into a grayish disk which was either attached to the surface of the anterior capsule of the lens or rested in the lower part of the anterior chamber. In a number of my cases the absorption of the coagulum progressed steadily till it had entirely disappeared, but in others it was interrupted by an increase in the inflammatory action, manifested by a new exudation of fibrinous matter. This was always accompanied by an increase or a return of the pain in the eye and a diminution of the size of the pupil. In several of my cases such relapses occurred, and two or three weeks elapsed before the fibrinous exudation was entirely absorbed. With the beginning of the absorption of the fibrinous substance in the anterior chamber there was always associated a marked decrease in the congestion of the vessels of the ocular conjunctiva, and by the time the exudation had disappeared only a moderate ciliary injection remained, which usually continued for some weeks more. Posterior synechia remained in most cases; and even in those cases in which the pupil had been kept moderately dilated throughout the course of the disease adhesions between the pupillary margin and the lens capsule could not be entirely prevented. The ophthalmoscopic examination which was always made, as soon as the pupil was free, showed in every case some diffuse opacity of the vitreous body and in many cases there were also present membranous opacities of varying density. In some cases the outline of disk was obliterated and the retinal veins were as a rule found congested and tortuous. Changes in the choroid could not be seen in any of the cases. The period required for the complete clearing up of the vitreous body varied from two to six months, and in a few of the cases some fleeting opacities remained as long as the patient was under observation. In most of the cases the sight was completely restored, while in a few it remained somewhat impaired.

In only a few of the cases were both eyes attacked simultaneously, but in several the second eye became affected before the first had entirely recovered. In other cases the second eye was attacked by the same disease a year or two after the first, while in still others the unaffected eye remained healthy as long as the patient was under observation. Relapses were quite frequent, and in some of my cases one or the other eye would be attacked almost every year. The relapses were, however, always of a milder type than the initial attack and yielded more speedily to treatment.

From the above it will be seen that the great majority of my cases of gonorrhoic irido-choroiditis presented the features not infrequently seen in cases of irido choroiditis following idiopathic chronic articular rheumatism, and that the gonorrhoic form has no symptoms peculiar to it.

Comparing my experience with that of the writers on this subject, I find that while it is in entire accord with Mackenzie[1] it differs from that of Lawrence and Wordsworth,[2] whose cases were characterized by the absence of exudation in the anterior chamber. In almost all of the more recently published treatises on the diseases of the eye, gonorrhœa is recognized as one of the causes of iritis, but mention of the form of this disease is made only by Wecker[3] and by Jacobson.[4] The former says that it is made up of both the serous and plastic forms and is readily cured by appropriate treatment. The latter, that it presented itself usually in the form of iritis simplex; abundant fibrinous exudation he saw but seldom.

In the treatment of this affection I have at various times employed nearly all the remedies that have been suggested for inflammation of the uveal tract. Instillations of a strong solution of the sulphate of atropine and

[1] Op. cit., p. 534.

[4] Beziehungen der Veränderungen und Erkrankungen des Sehorgans zu Allgemeinleiden, p. 89.

of the muriate of cocaine were, of course, made frequently from the day the case came under treatment till all inflammatory symptoms had disappeared. In only a few cases were cold applications to the lids of any benefit, while, on the other hand, warm fomentations seemed to soothe the eye. For the relief of the excessive pain which was present during the first week of the disease I have applied from six to twelve leeches to the temple, and have given internally the salicylate of sodium in twenty-grain doses every two hours till the physiological effects of this drug were produced; after that it was used in smaller doses at longer intervals. Not unfrequently it was necessary to give in addition morphine or antipyrine at night in order to procure sleep. Quinine in large doses was given occasionally to patients who could not take the salicylate of sodium, and in some cases with apparent benefit. In former years I gave in such cases calomel and other preparations of mercury, but have abandoned this treatment, as the remedies above mentioned seem to give more speedy relief. After the subsidence of the pain I have given the iodide of potassium or the muriate of pilocarpin with a view of clearing up the vitreous body, and this was usually accomplished in the course of some months.

CHLORALAMID AS A HYPNOTIC IN THE TREATMENT OF MENTAL DISEASES.

By D. F. KINNIER, M.D.,

NEW YORK CITY.

CHLORALAMID, which has been recently introduced as a new hypnotic in the treatment of mental diseases has lately been much prescribed and with varying results.

It has a slightly bitter taste, and can be given in the form of a powder placed on the tongue, or may be given dissolved in alcohol or water. In order to test the efficacy of this drug in the treatment of the insane, it was given in a number of cases, some of which are noted with the results obtained.

CASE I. *Acute Mania.*—F. H——, a woman, aged thirty-seven. The first dose given consisted of thirty-five grains, which produced three and one-half hours' sleep at the end of two hours. On the second, third, and fourth occasions, thirty-five grains were given, resulting in four and one-quarter hours' sleep at the end of one hour. On the fifth occasion the patient was more excitable and restless than on either of the previous occasions, and forty-five grains were given, producing three hours' sleep at the end of an hour. Three more observations were made, the dose given being forty five grains each time, and produced five hours' sleep at the end of forty-five minutes. Sulfonal, bromide, and chloral were also given in this case, but with less satisfactory results than were obtained from the use of chloralamid.

CASE II. *Acute Mania.*—J. R——, a woman, aged thirty-five. Had periodic attacks of excitement, during which she raved, swore, and shouted. Refused food and was fed by tube. Patient received thirty five grains, and received four hours' restless sleep at the end of two hours. The second time she received forty grains, and five hours' sleep resulted at the end of one hour. The third consisted of forty-five grains, which produced six hours' sleep at the end of thirty-five minutes. The next time she was given forty-five grains, which produced five hours' sleep at the end of forty minutes. Patient was occasionally restless at night, and several observations were made with doses of forty-five grains, resulting in five or six hours' restless sleep at the end of one hour.

CASE III. *Acute Mania.*—S. H——, a woman, aged thirty-six. Gives a history of intemperance, and has at present active hallucinations of hearing. Has marked periods of excitement, when she calls on God and the doctors to kill her, as she wishes to die. Was given twenty-five grains, which had no effect. Six hours later she was given thirty-five grains, which resulted in one hour's sleep at the end of two hours. On each of the three following nights she was given forty-five grains, resulting in four hours' sleep at the end of one hour. The bromides and chloral seemed to produce better effects in this case than either chloralamid or sulfonal.

CASE IV. *Acute Mania.*—F. H——, a woman, aged thirty-three. Previous to taking chloralamid she had obtained a fair night's rest with thirty-five grains of sulfonal. Becoming quiet the patient received no sedatives until she again became excitable. She was now given thirty-five grains of chloralamid, and sleep for three hours resulted at the end of one hour and a quarter. On awaking she was quite excitable, and was given a dose of forty-five grains, resulting in four hours' sleep at the end of forty-five minutes. Third dose was forty-five grains, which produced five hours' sleep at the end of half an hour. The three days following, her mania seemed to have lost most of its delirious character, and during this period she received three doses of thirty-five grains each, which resulted in five hours' sleep at the end of forty-five minutes. The patient becoming quiet, the medicine was not given for several days, at the end of which time she was occasionally restless at night, but forty-five grains administered at 7 P.M. usually gave her a comfortable night's rest.

CASE V. *Acute Mania.*—H. A——, a woman, aged thirty-four. She was restless, excitable, and continually trying to get out of bed. She slept little the first night, and the following morning was much excited, rolling about in the bed and pulling at the bedclothes. She received thirty five grains, which produced two and one-half hours' sleep at the end of one hour. In the evening she was apparently less maniacal, and was again given thirty-five grains, resulting in three hours' sleep at the end of forty minutes. The next dose was forty-five grains, resulting in three hours' sleep at the end of an hour. The two nights following she was so maniacal that hypodermic medication was resorted to. The next few nights she was noisy and restless, but her maniacal condition was less marked. She occasionally received forty-five-grain doses, which produced between five and six hours' sleep at the end of an hour.

CASE VI. *Chronic Mania.*—B. S——, a woman, aged thirty-five. On admission was maniacal and assaulting; her sleep power seemed to have gone; she would walk up and down the room beating on the walls the greater part of the night. She was first given thirty-five grains, resulting in one hour's sleep at the end of an hour and a quarter. On the second occasion she received forty-five grains, which resulted in three hours' sleep, at the end of forty minutes. The third and fourth doses were thirty-five grains, which produced two hours' sleep at the end of forty-five minutes. She was given four doses of forty-five grains each, resulting in from five and one-half to seven hours' sleep at the end of three quarters of an hour to an hour.

CASE VII. *Chronic Mania.*—E. F——, a woman, aged forty, with a history of intemperance. She has been noisy and restless for the past few nights, and received on each occasion thirty-five grains of sulfonal, which produced six or seven hours' restless sleep. She was quiet for a few nights, but again becoming noisy, she was given, for the first time, thirty-five grains of chloralamid, which resulted in five hours' restless sleep at the end of an hour. She afterward received three doses of forty five grains each, and four doses of thirty-five grains each, the former producing five hours' sleep at the end of forty minutes, the latter resulting in four hours' sleep at the end of an hour.

CASE VIII. *Primary Dementia.*—A. B——, a woman, aged twenty-two, admitted in a state of partial stupor. A few days later she became more stupid, apathetic, and apparently demented, and wholly unable to care for herself. Later she was observed to speak and notice her surroundings, and seemed to recover her speech, and appeared brighter and worked about the ward. At times when helping in ward work she was observed to be excitable, especially if interfered with. She quarrelled with a patient, and suddenly became violent and assault-

ing; she was given hypodermic injection of hyoscyamine. That evening she was restless and noisy, and received forty-five grains of chloralamid, which produced four hours' sleep at the end of one hour. She next received forty grains, which resulted in four hours' sleep at the end of thirty-five minutes. She again relapsed into a state of stupor which continued for a few days, and was followed by a period of excitement, for which, on five occasions she received forty-five-grain doses, resulting in four to five hours' sleep at the end of thirty-five minutes.

CASE IX. *Senile Dementia.*—J. E——, a woman, aged sixty-three. First night received a dose of twenty-five grains, sleep resulting in two hours and continuing for three and one-half hours. Second night no medicine was given. Third night she was noisy and restless, and was given thirty-five grains, resulting in five hours' sleep at the end of forty minutes. Fourth, fifth, and sixth nights she received forty-five grains, and slept for six hours at the end of an hour. She later occasionally received doses of thirty-five grains, which produced five to six hours' sleep at the end of an hour.

CASE X. *Secondary Dementia.*—A woman, aged thirty-eight. Five observations were made, the doses ranging from twenty-five to forty-five grains, producing two to five hours' sleep at the end of one hour, and also at the end of thirty-five minutes.

CASE XI. *Chronic Insanity.*—M. S——, a woman, aged sixty, was generally restless, and noisy at times, during the night, unless some sleep-producing drug was administered. Three doses of thirty five grains each were given on alternate nights, which resulted in five hours' sleep at the end of an hour.

CASE XII. *Acute Melancholia.*—A. N——, a woman, aged twenty-seven, was much agitated and in fear of being killed. Melancholy, and refused her food as she thought it was poison. Fed three times with tube. Became restless and sleepless at night, with melancholic agitation during the day. Would frequently get out of bed at night, and, pounding on the door, would say there were people in the room who wished to kill her. The first night she received thirty-five grains and slept four hours at the end of thirty-five minutes. The next night she received forty-five grains, sleep resulting for five hours at the end of half an hour. The third and fourth nights she received thirty-five grains, sleep resulting for five hours at the end of half an hour. The fifth night she received forty grains, and slept six hours at the end of one hour.

The following day she appeared quite calm and orderly, but was slightly depressed. She was occasionally restless at night, but when given thirty-five grains she obtained from five to six hours' sleep at the end of an hour.

CASE XIII. *Acute Melancholia.*—J. N——, a woman, aged twenty-four. Received on first occasion twenty-five grains at 7 P.M.; sleep occurred at 8 P.M., and continued two hours. She was next given forty-five grains, and three hours' sleep resulted at the end of one hour. Third dose same as second, result similar. She was given forty-five grains on several occasions afterward, and sleep resulted at the end of forty-five minutes for five or six hours.

CASE XIV. *Acute Melancholia.*—A woman, aged thirty-two. Patient received either chloral and bromide or sulfonal at bedtime. She was given thirty grains of chloralamid on three successive nights, resulting, in half an hour to an hour, in sleep amounting to five and six hours. On the fourth night she received forty-five grains, which produced seven hours' sleep in half an hour, of a restless character.

CASE XV. *Acute Melancholia.*—A woman, aged thirty-one. Very much agitated on admission and quite restless during the day. She was immediately given thirty-five grains, resulting in three hours' sleep at the end of forty minutes. She appeared frenzied in the evening, and she was given forty-five grains, which produced four hours' sleep at the end of an hour.

On the three next nights she received three doses of forty-five grains each, resulting in six hours' sleep at the end of forty-five minutes. She afterward received occasionally thirty-five grains, which resulted in five to six hours' sleep at about the end of an hour.

The hypnotic effect of chloralamid seemed in many instances to be too slowly produced, especially in maniacal cases characterized by much violence. When the drug did produce sleep in these cases, the sleep was of a restless character. On the contrary, in some cases of melancholia the drug seemed to act very well and in a short space of time; but I do not think its hypnotic effects are rapid enough to warrant its use in cases of acute delirious mania or in cases of great excitement where sleep is urgently required.

If given in large doses, sixty grains for instance, there is no doubt sleep will result in twenty or thirty minutes, but such large doses are apt to produce vomiting, vertigo, and other disagreeable symptoms. In beginning the use of this drug it is preferable to give twenty-five grains and increase to forty-five, which dose may be given without any unpleasant symptoms as a rule.

When the chemistry and physiological action of this drug is better understood than it is at present, we may look for better results, and although disappointing in some cases, yet in many cases it will be found a valuable hypnotic.

A METHOD OF ARTIFICIAL INFANT FEEDING.[1]

BY GEORGE B. FOWLER, M.D.,

NEW YORK.

THE human infant is an object of great solicitude. Every baby born has that interest centred upon him as though he were the first and last of his kind. He is a very dependent thing. Prior to birth he is part of another anatomy and derives his nutrition from the general supply. Subsequently, when he attempts a separate existence, he is apt to find himself the prey of innumerable and unpronounceable bacteria, and the target of domestic ignorance and commercial enterprise in the way of food.

As soon as the child severs its uterine connection it naturally establishes mammary union, and, under normal conditions, upon that monotonous supply it depends and thrives.

It is wholly unnecessary to state that indigestion and diarrhœa in children are serious matters, and to quote statistics in proof. All of this is perfectly well known, and the repetition of it need no longer serve to pad a paper on the subject. What we now want is the result of practical clinical experience and methods of cure. I strongly favor common-sense success against theoretical procedures based upon the microscopic examination of fæces and bacterial cultures. As far as I am informed, these latter have as yet added very little to our therapeutics as applied to internal medicine.

When it becomes necessary to resort to artificial alimentation in infants we must concoct a food which shall be nutritious, is easy to prepare, and whose physical and chemical characters shall be adapted to the delicate conditions which it has to meet. Cow's milk, of course, is our mainstay; it ever has been and now is. There is every reason why it should be. The only trouble with cow's milk is the fact that it is designed for a more perfect animal than a baby. The calf is born with far greater physical development than the human offspring.

All are agreed that the important difference between cow's and human milk is the excess of casein that it (the former) contains, and that it forms a too firm and insoluble clot. Hence the various devices designed to modify the solidity of the casein clot, and to adapt cow's milk to the delicate requirements of infants and invalids. I am quite familiar with the methods generally in use for this purpose, but have now come almost exclusively to employ

[1] Read before the Obstetrical Society of New York, May 20, 1890.

that which it is the object of this brief paper to describe. It is as follows :

Put four tablespoonfuls of rice into three pints of water, and boil half an hour ; then set aside on back of range to simmer during the day, water being occasionally added by the cook to maintain the original three pints. At night strain through a colander and place on ice. When cold a paste is formed. Three tablespoonfuls of this paste are added to each nursing-bottle (half pint) of milk, and fed during the next day, a fresh supply of rice-paste being under way in the meantime. Should there be constipation I use farina, prepared in same way, and used in the same proportion. Rice is astringent, farina laxative.

From a series of careful experiments with these pastes I am convinced that the hydrated starch granules interpose themselves between the particles of casein, and prevent the formation of solid clots. By this process we do not dilute the cow's milk, but, on the other hand, soften it, and add a constituent, carbohydrate, in which, compared with mothers' milk, it is weak. No fear may be had but that starch thus treated and administered will be digested by a child of three, or even two months. My success with this preparation has been such that I offer it to the profession with great confidence.

Clinical Department.

A REMARKABLE CASE OF ACUTE POISONING FROM THE EXTERNAL USE OF THE TINCTURE OF IODINE.

By GEORGE THOMAS JACKSON, M.D.,

VISITING DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITALS.

On May 1st there was received into my service in the Randall's Island Female Hospital a woman with the following history :

Mrs. A——, about fifty years of age ; Irish. General health is good. The patient is enormously fat, and the skin is fair, thin, and soft. She says that three days before coming into the hospital, she had a pain in the right side of the abdomen, for the relief of which she had a little girl rub into her side "half of five cents' worth of iodine." This was done at nine o'clock in the evening. At one o'clock she awoke with a feeling of great nausea, and vomited six or seven times a yellow fluid that was very acid, so that it burnt her throat. The next morning she found that there was a good deal of redness of her right arm, and a large blister upon it. The dermatitis spread rapidly from here, and within twenty-four hours it had involved the face, neck, shoulders, left arm, and appeared in patches on the trunk. Then bullæ appeared on the legs, and in this condition she was admitted to the hospital.

When first seen by me, the eruption was evidently subsiding. The arms, face, neck, and trunk, showed evidence of a lessening dermatitis, being red and scaly. The face was somewhat swollen, and there was a yellowish green crust on the right forearm. On both legs were a number of irregular shaped figures with a red outline, which without doubt were the sites of the bullæ. There were also one or two bullæ with turbid contents. The tongue was greatly swollen, red, and glazed. The patient complained of a feeling of prostration, of great burning and discomfort in the skin, of complete anorexia, and pain, and burning at all attempts at deglutition. She also said that her throat and stomach felt raw.

She was ordered a strict milk diet, water *ad lib.*, an alkaline diuretic, and a mouth wash of chlorate of potash. Locally it was directed that she be smeared over with vaseline, and powdered with corn-starch powder, two or three times a day. Under this plan of treatment she rapidly improved, as far as her skin was concerned, so that within two weeks, there was only a slight erythema of the skin remaining.

The disturbance of her digestion was not so easily controlled. She was troubled with vomiting so that whatever she drank was returned in a short time. But within three weeks' time this all passed away, and she was discharged in good health.

In this case it is hard to believe that the profound constitutional disturbance was not due to the patient having swallowed the iodine. But this, she positively denies. If her statement is true, the case is certainly a remarkable instance of idiosyncrasy toward iodine.

14 East Thirty-first Street.

PHENACETINE IN INSOMNIA.

Dr. F. Peyre Porcher, of Charleston, S. C., writes : "I desire to call special attention to the extreme value of phenacetine as a remedy for insomnia. Given at night in a little water it is tasteless, innocuous, and induces sleep. I am confident, also, after repeated trials, that it is the best and most unobjectionable substitute for morphia. It causes sleep when, of course, pain is in abeyance, unless the pain be more than ordinary, and morphia hypodermically may then be required. The remedy may be repeated and the dose increased to seven or ten grains.

"Suffering from chronic rheumatism of the forearm, I have tested it repeatedly in my own person, and have given it to many who have suffered from insomnia, or inability to sleep from any transient cause, fatigue, nervousness, excitement, etc., in either sex.

"I see that sulphonal has recently been advised. No accusations have ever been made against phenacetine, whereas, sulphonal, antipyrine, and antifebrine have at times been found to possess toxic qualities

"I have made comparative tests of the four agents, and believe that phenacetine has a great future for the two purposes above indicated. It may also be used in children who are sleepless from fever or excitement."

Progress of Medical Science.

Tissue Metabolism in Cancer.—Dr. F. Müller has made some careful comparative observations upon the urine in cases of cancer and other wasting diseases, and in simple starvation. He finds that in the cancerous the excretion of nitrogen far exceeds the amount ingested, and infers that this excess must in consequence be derived from the disintegration of the albuminoids of the body. However, in two out of seven cases this loss was not greater than occurred in other individuals similarly insufficiently nourished. The chlorides were, on the other hand, notably diminished, a fact, he thinks, pointing to the source of the excreted nitrogen—viz., from the organ albumin and not from the circulating albumin. Obviously, however, many diseases share, with carcinoma, in this disintegrating process, as Müller showed to be the case in chronic febrile affections, especially severe forms of malaria, in leukæmia and pernicious anæmia. Previous observers do not coincide in their statements on this head as regards leukæmia. Voit and Pettenkofer found no marked evidence of increased metabolism in this affection, and Fleischer and Penzoldt concurred in this so far as regards mild cases. But in severe cases the last-named find the urea to be increased both absolutely and relatively. Sticker and Klemperer arrived at the same conclusion. Respecting pernicious anæmia, there is a concurrence of testimony in support of increased nitrogenous excretion. Reverting to cancer, this evidence, Müller thinks, goes to prove that malignant disease excites the formation of metabolic products which are poisonous to the organism. He points out that cachexia develops in the cases of malignant growths, no matter how limited, and without their involving any important organ ; whereas a non-malignant tumor may attain great dimensions without affecting the excretion of urea. At the same time no

such poison or ferment destructive of albumin can be isolated from cancerous tumors, although the fact pointed out by Feltz, that the urine of the cancerous is more toxic to animals than that of healthy individuals, is, with other facts, highly suggestive of that view.—*The Lancet*, May 10, 1890.

Kola-nut for Sea-sickness.—Dr. C. W. Hamilton, of the British Navy, writes to the *British Medical Journal* of May 10, 1890, that he has found the seed of the kola (*Sterculia acuminata*) a most successful remedy in sea-sickness. From half to one drachm of the seed was slowly chewed, and in about half an hour the distressing symptoms of the malady gradually disappeared. The writer had never found any drug to act as well as this, and believes that further trials will prove it to be an effectual remedy for sea-sickness.

Sodium Salicylate in the Treatment of Chorea.—In an article in the *Bulletin Général de Thérapeutique*, No. 16, 1890, Dr. Dresch speaks very favorably of the action of salicylate of sodium in cases of chorea. The disease, he says, is of greater gravity than is generally supposed, for it not infrequently causes death either directly or indirectly. The importance, therefore, of an intelligent and active therapy is manifest. He believes that chorea is a microbial disease, the micro-organism of which is probably of the same family as that of rheumatism. The choreic movements are to be regarded as reflexes provoked by the presence in the tissues of the specific microbe, and are similar to the cough of pertussis, the spasms of tetanus, the premonitory chill of certain fevers, etc. Having these views as to the nature of the disease, he adapts his therapeutic measures to them, as far as it is possible to do so, although he admits freely the inefficiency of salicylic acid as a microbicide. The treatment should be begun at the earliest possible moment, and should be energetic, whether the beginning of the disease be severe or mild. The drug is not given as a germicide or as antirheumatic, but rather because of its action upon the medulla and cord, where it affects the motor centres as well as the sensory, thus restraining the movements of chorea as well as the pain of rheumatism. It is probable also that it would act equally well in diminishing the severity of the paroxysm in whooping-cough, though the author has never tried it in that affection. It is to this sedative effect of the drug that he attributes the fact that he has never seen any excessively severe cases since beginning its use, and has not been obliged to have recourse to any of those agents which calm the paroxysms only by stupefying the patient. But another great advantage possessed by the salicylate is that it increases the elimination of waste products, being, like benzoic acid and its derivatives, a solvent; in other words, it opens the kidneys instead of closing them as do quinine and antipyrine, which are so often given in chorea. It is evident that the choreic movements must greatly augment the amount of waste products, both muscular and nervous, thrown into the circulation, which products are toxic and of themselves excite convulsions. It is of the utmost importance, therefore, that any remedy given for the disease should favor the elimination of these materials by the kidneys and other emunctories. Dr. Dresch has found the salicylate well borne in most cases, a child of twelve years taking without trouble as much as sixty grains in the twenty-four hours, the only precaution being to give the drug in small and repeated doses well diluted with slightly alkaline water. It is not usually necessary to continue the use of the remedy more than eight or ten days. During the first period of the disease the patient should be kept in bed in a well ventilated room at an even temperature, and noise should be avoided as far as possible. A milk diet is the best if it is acceptable to the patient, but beef tea is not to be recommended. An enema of tepid water once a day is useful, but should not be insisted upon if the patient objects strenuously. Nothing, indeed, should be done that is liable to excite the child. As the disease begins to subside the treatment should keep pace with it, the child being allowed to get up and gradually resume his usual diet and amuse himself in his accustomed way. The author objects decidedly to sea-baths.

Dr. Luys' Process for Inducing Hypnotism.—In view of the uncertainty and the frequent failures which accompany the use of brilliant substances, and particularly, too, of the sustained attention and the fatigue required to develop hypnotism in new patients, Dr. Luys conceived the idea of presenting the brilliant substance mechanically instead of holding it in his own hands, giving it at the same time a rotatory motion in order to increase its influence. A patient required to keep his eyes fixed on bright particles which are revolving before him feels a sense of weariness after one or two minutes; he is insensibly fascinated, and to one's surprise one sees him gradually close his eyes and lie back in his chair, like a person falling fast asleep; he is then in the state of lethargy. Since Dr. Luys took to using revolving mirrors in order to produce hypnotic sleep he has never failed to be satisfied with the results. After two or three minutes patients of either sex who are operated on show themselves equally quick in feeling the effect, the young and the old alike. It can also be shown that this sleep, mechanically produced, is not, as might be expected, a natural sleep, but, on the contrary, it is a peculiar kind of sleep, for which he suggests the term mechanical sleep. It brings about in the nervous system a very special condition, which is distinguished by a general anæsthesia of the integuments, a catalepsy of the muscles, and a tendency to act upon any suggestions made. The importance of the practical results of this new method, which brings about hypnotization without fatigue and of prolonged duration, while it also enables one to subject several patients at once to the influence of hypnotism, is equally comprehended. Every day by its application he can have eight or ten patients in his laboratory who are all hypnotized together by the influence of a single revolving mirror placed in the centre of them. There is also an extremely interesting point to be deduced from the use of this method, viz., that by being thus able to produce without difficulty a state of trance in a number of patients, the patients are brought to a special condition of the nerves, by means of which they become ready to accept other influences and to undergo therapeutic influence. By this means he has been enabled to bring about a series of valuable practical results, such as the stopping of sharp pains, the restoration of sleep to persons tortured by prolonged insomnia, the renewal of the powers of locomotion in paralytics, and, in short, a number of improvements of very distinct character and of long duration. Besides, there is this in favor of the new methods which he has adopted, that out of two hundred patients actually brought under his notice he has never observed a single accident. The process, therefore, is perfectly harmless, and when employed with skill and prudence it can produce no harmful effects in the persons experimented upon.—*Fortnightly Review.*

Circumscribed Gangrene Following Vaccination.—At a recent meeting of the French Society of Dermatology and Syphilography, Dr. Balzer reported the case of a woman, twenty-three years of age, who had had malignant syphilis in early life, in whom, a few days after vaccination, there appeared at the site of the pustule a slough, which eventually attained the size of a five-franc piece. It was nearly four months before the slough became detached, leaving an ulcer that took two weeks to heal. The speaker thought this complication was not due to the syphilis alone, but rather to the accidental introduction of septic organisms at the vaccination, the soil being most favorable for their development. The quality of the virus was above suspicion, since this case was the only one of the kind in a number of persons who were vaccinated at the same time and with the same vaccine material. —*La France Médicale*, April 25, 1890.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 12, 1890.

THE UNITED STATES AND ITS DOCTORS.

THERE is certainly no more curious social phenomenon than that of the extraordinary popularity of the medical calling in this country as a means of securing a livelihood.

The subject is one that is often dwelt upon, but we doubt if many even yet realize the grotesque misproportion which medicine in the United States holds to other bread-winning occupations. Here are some of the naked facts in the matter:

France has 38,000,000 of population, 11,995 doctors, while it graduates 624 medical students in one year.

Germany has 45,000,000 of population, about thirty thousand doctors, and graduates 935 students in one year.

The United States has about sixty millions of population, nearly one hundred thousand doctors, 13,091 medical students, and graduates 3,740 students in one year.

Germany, which has relatively less than half as many doctors as America, is already groaning over its surplus. When one compares France with this country, the excess of medical men here seems most astonishing. A comparison of the United States with European countries, in whatever way it is made, leads one to think that there is something almost morbid in our medical fecundity.

THE EXCRETION OF GLYCURONIC ACID.

THE time is now long past when the reduction of a copper salt by urine in alkaline solution was regarded as a positive indication of the presence of sugar (glucose) in the urine. By careful and prolonged observation and study, it has been shown that in many cases this reduction occurs when no trace of glucose is present. The result is that reduction tests are now looked upon as merely *negative* tests for glucose, the *positive* tests being the fermentation and phenyl-hydrazin tests. But what is the nature of these non-saccharine reducing agents? Slight reduction may be produced by many substances which occur in normal or diseased urine, as, for instance, by uric acid, kreatinin, kreatin, allantoin, mucin and bile pigment, but not much attention need be paid to such slight reduction because the occurrence of glucose, for which these substances might be mistaken, in such small quantities, and for only a short time, would not indicate serious disease—diabetes mellitus being characterized by the *persistence* of *considerable quantities* of glucose in the urine.

In certain cases, however, large quantities of a powerfully reducing substance are found to be constantly present in the urine of persons who exhibit no symptoms of ill-health. Such persons were formerly considered to be the subjects of obscure diabetes mellitus, reduction-tests alone being relied upon. Further investigations, however, show that in certain instances urine, which powerfully reduces test solutions, does not ferment at all with yeast. The study of such urine has led to the isolation of the reducing substance, which has been named glycuronic acid.

In the *British Medical Journal*, January 25, 1890, p. 169, Dr. Ashdown publishes some interesting notes concerning this compound. A large quantity of urine containing it is evaporated down to a sirup, and treated with barium hydrate, and afterward with sulphuric acid, when crystals of the anhydride form are obtained. It is very soluble in water, and appears in urine combined with urea, reducing copper, bismuth, mercury, and silver solutions. In its different combinations it affects the ray of polarized light differently, so that it cannot be distinguished from glucose in urine by this method. It does not ferment with yeast. (It is not probable that it gives the phenyl-hydrazin test, a method of which the author appears to be ignorant.)

Glycuronic acid appears in the urine after the administration of chloral hydrate, croton chloral, camphor, etc., and of morphia and chloroform. Appearance after the use of morphia, by mouth or subcutaneous injection, is the rule, while occasionally the use of chloroform is not followed by the presence of any reducing substance in the urine. Glucose is not found, as was formerly supposed, after the administration of these drugs. Ether does not, as far as known, give any reducing powers to the urine.

As the result of certain experiments described, in which section of the renal nerves of one side was made, he is led to believe that the glycuronic acid which appears in the urine is not simply exuded from the blood into the kidney ducts, but that its secretion is the result of some distinct chemical process presided over by the renal epithelium.

But does glycuronic acid occur in the urine of healthy persons who have not been taking drugs? After a prolonged search, involving several hundred cases of healthy and diseased persons, Dr. Ashdown found one case in which very large quantities of glycuronic acid were passed daily, by a man about twenty-four years of age, who was apparently in excellent health and gave no evidence of diabetes mellitus. The urine was not increased in quantity nor in density.

This case he believes to be the first and only one recorded in which glycuronic acid was shown to be present in large quantity. For the benefit of our readers, however, we may refer to the very interesting case discussed by Drs. Brune (*Boston Medical and Surgical Journal*, December 30, 1886, and January 27, 1887). Marshall (*Medical News*, January 8, 1887), and Bond (*Medical News*, August 6, 1887), in which an apparently healthy man was refused by several insurance companies because his urine contained, constantly, large quantities of a powerful reducing substance which did not ferment with yeast, and did not give the phenyl-hydrazin test for sugar. Careful study was bestowed upon it, and it was found to be an acid, but whether it was identical with glycuronic acid or not, had not been determined.

As Dr. Ashdown suggests, cases classed as diabetic may frequently belong to the "glycuronic" class, and, likewise, urine may at times contain both glucose and glycuronic acid, when the tests for each might be somewhat obscured by the reaction of the other. There is no reason why other powerful reducing substances than glycuronic acid should not occasionally occur in the urine of healthy persons.

THE JAPANESE MEDICAL CONGRESS.

In the early part of April of this year the first national assembly of Japanese physicians was held in Tokio. The attendance was estimated at about three hundred, all of them being Japanese, the foreign physicians resident in Tokio for some reason taking no part in the Congress. The sessions lasted an entire week, and very many papers were read, but none of them, if we may judge from the titles alone, offered anything of special interest to Western medical men, as giving them any information concerning the diseases peculiar to Japan or the special conditions affecting health in that country. In commenting upon this lack of distinctly national papers, a writer in the *Sei-I-Kwai Medical Journal* says that it shows a want of appreciation of the fact that Western medicine must be not adopted simply, but adapted to the conditions present in the East. The natural history of a people and their constitutional peculiarities should be taken into consideration when it is a question of treating the diseases which affect them. The basis of scientific medicine is the same for all lands and all peoples, but the superstructure must differ with varying conditions of constitution, climate, etc. In all new countries (new in relation to European civilization) the fundamentals of medical science must be taught by foreigners, but when the natives are themselves proficient in these the further development of the science in their own country must be left to them. They know their people and they know the general principles of the healing art, and it is for them to apply their knowledge in these respects in such a way as to obtain the best results. The foreign physician has then fulfilled his mission, and can safely turn over the further development of his art to his native pupils.

News of the Week.

Prescribing Patented Medicines.— One of the questions proposed for discussion at the annual meeting, recently held, of one of the State medical societies, was the following: Sulphonal, antipyrin, and the like are patented medicines. It is contrary to the spirit of the code of ethics for physicians to prescribe them, or in any way to promote their use. They are not patented in Germany, where they are manufactured, and are highly recommended by the leading physicians in Europe. How can this hindrance to their employment by physicians in this country be removed? Another was to define the form of advertising which is forbidden by the code of ethics. Unfortunately, none of the members seemed disposed to discuss these interesting points, and consequently they went unanswered.

Medical Education in the Homœopathic Colleges.— The American Institute of Homœopathy, at its forty-seventh annual session, held at Waukesha, Wis., last month, upon the suggestion of its collegiate committee, representing the thirteen colleges of this school, voted to require a four years' course of medical study from all students entering its colleges after the session of 1891–92.

The Cholera in Spain.—Cholera has reappeared in the province of Valencia, which was at one time reported free from the disease. Cases are also said to have been discovered in Portugal and France, but these were probably of simple cholera and not of the epidemic form. The greatest danger to this country, should the disease prove to be Asiatic cholera, will probably be through Cuba, as that island is in very close relations with Barcelona, where there have been numerous cases reported.

The Journal of Balneology would be more honest if it gave credit for the numerous articles taken bodily from our columns.

Yellow Fever.—Several cases of yellow fever occurred recently at Malaga in the persons of travellers coming from infected regions.

Rules of the Washington State Board of Medical Examiners.—*Section* 1. Any applicant for examination and license to practise medicine in this State, who is a graduate of over five years' standing before making application for such license, shall be considered an "old practitioner," and any applicant who is a graduate of less than five years shall be considered a "recent graduate."

Section 2. Applicants who are old practitioners shall be required to obtain a minimum marking of sixty-five per cent. in the practice of medicine, surgery, materia medica, obstetrics, and diseases of women and children. A minimum marking of thirty-five per cent. in physiology, anatomy, and pathology. A minimum marking of twenty-five per cent. in chemistry, histology, medical jurisprudence, preventative medicine, diseases of the eye and ear, and diseases of the nervous system.

Section 3. Applicants who are "recent graduates" shall be required to obtain a minimum marking of sixty-five per cent. in the practice of surgery, materia medica, obstetrics, and diseases of women and children. A minimum marking of fifty per cent. in anatomy, physiology, pathology, and diseases of the eye and ear. A minimum marking of thirty-five per cent. in histology, preventative medicine, chemistry, and medical jurisprudence.

Section 4. No applicant shall be issued a license to practise whose general average in all the subjects in which he is examined is less than sixty-five per cent.

The board has adopted the form of license now in vogue in Minnesota.

St. Vincent's Hospital, in this city, is to be enlarged by a wing to extend along Twelfth Street from the wall of the present building on that street to the corner of Seventh Avenue. The wing is to be built to conform with the style of the Twelfth Street frontage, which was put up in 1882. The building will be of brick with brown stone trimmings, four stories high, and of simple but substantial style. The addition will be used for purposes similar to the uses to which the present building on Twelfth Street is put, being divided into small wards and private rooms. The cost of the new wing will be $60,000.

Pyoctanin, or Methyl Violet, in Surgical Practice.—Experience in the surgical policlinik of Dr. Kölliker, of Strasburg, with the use of pyoctanin has given entirely negative or unfavorable results. In purulent processes and granulating wounds little improvement was obtained, while the intense staining of the parts is very disagreeable to both patient and operator.

The Medical Care of the Poor in Richmond.—The city of Richmond, Va., with 100,000 inhabitants, has, says the *Virginia Medical Monthly*, no city hospital and no public city dispensary. This must be a halcyon spot for the young doctor, if all the evils of unlimited dispensaries and hospitals and poor relief are true. New York has sixteen times the population of Richmond, but it has fifty times its means of caring for the sick poor, and treats 300,000 or more people every year for nothing. We are glad the Richmond doctors are urging the need of more hospitals and dispensaries, but when the "boom" comes let them not complain.

The Legal Enforcement of Female Medical Attendants upon Insane Asylums.—The investigation of the Cook County Insane Hospital, in 1889, demonstrated, says the *Medical Standard*, "the dangerous folly of making sex a legal prerequisite to appointment to a medical position. A female physician appointed on such principles neglected her patients to such an extent that they were devoured by vermin and scourged by scurvy. Despite these serious neglects this physician was supported by hysterical female societies, simply because she was a woman." This experience is quite in accordance with the views expressed by the MEDICAL RECORD. Medical women can be of much service in an insane asylum, as consultants or internes; but it is not just or necessary to force them upon the management.

The Woman's Medical College of this City will move into a new and commodious building next fall.

Railroad Surgeons.—It appears that some railroad companies hire doctors by contract and get a large amount of work from them, including expert testimony, for very small sums of money. We do not see what can be done about it as long as there are plenty of men willing to make the contracts. The West Virginia Medical Society, however, has

"*Resolved*, That this society appoint a committee to take such steps as will be necessary to bring to the attention of societies of adjoining States, and the American Medical Association, the relations assumed by railroad corporations in establishing systems of contract surgeons, and the rules adopted for the government of their surgeons, contrary to the spirit and letter of the code of ethics; and the small compensation given for such unlimited services; all of which is detrimental to the general interests of the profession by lowering the value of medical services."

Records of the Medical Department of the Confederate Army.—Dr. Joseph Jones, Surgeon-General of the United Confederate Veterans, has issued the following circular: "A movement is on foot, under an organization known as the Association of United Confederate Veterans, whose objects are to secure, among other things, the following items: 1. Name, age, nativity, date of commission in the Confederate Army, nature and length of the service of each and every member of the medical corps of the Confederate States Army. 2. Obituary notices and records of all deceased members of the medical corps of the Confederate Army. 3. The titles and copies of all field and hospital reports of the medical corps of the Confederate Army. 4. Titles and copies of all published and unpublished reports relating to military surgery and all diseases of armies, camps, hospitals, and prisons. The object proposed to be accomplished by the Surgeon-General of the United Confederate Veterans is the collection, classification, preservation, and final publication of all the documents and facts bearing upon the history and labors of the medical corps of the Confederate States Army during the civil war of 1861–65. Everything which relates to this critical period of our national history which shall illustrate the patriotic, self-sacrificing, and scientific labors of the medical corps of the Confederate States Army, and which shall vindicate the truth of history, should be industriously collated, filed, and finally published. It is believed that invaluable documents are scattered over the whole land, in the hands of the survivors of the civil war of 1861–65, which will form the material for the correct delineation of the medical history of the corps which played so important a part in the great historic drama. Death is daily thinning our ranks, while time is laying its heavy hand upon the heads of those whose hair is already whitening with the advance of years and the burden of care. No delay, fellow-comrades, should be suffered in the collection and preservation of these precious documents. This task of collection of all documents, cases, facts relating to the medical history of the Confederate Army invites the immediate attention and co-operation of his honored comrades and beloved compatriots throughout the South."

Collapse Following the Administration of Sodium Salicylate.—Dr. A. G. Auld reports in *The Lancet* of June 14, 1890, two cases in which alarming symptoms of collapse followed the exhibition of salicylate of sodium for rheumatism. The dose in each case was about one hundred grains a day. The injurious effects were attributed by the author to impurities in the preparation used, and not to the drug itself.

Fresh Air Mission in St. Louis.—The St. Louis Bridge Company's Fresh Air Mission was opened a week or so ago, and from now until September 1st, women and children will be admitted after seven o'clock each evening, without charge, to the upper roadway of the bridge. For several years past this has been done by order of Dr. Taussig, the general manager of the bridge, and hundreds of persons have been thus enabled to take advantage, during the extremely sultry weather, of the fresh breeze which always blows from the river.

Dry Gangrene in a Child Two and a Half Years of Age.—Dr. C. M. Kelley writes that the account of this case which appeared in our issue of July 5th, was wrongly credited to himself, whereas the author was Dr. W. H. Hubbard, of Marion, Ind. The paper was read before the Delaware District Medical Society, and was ordered to be published. The Secretary of the Society, Dr. Kelley, forwarded the paper on behalf of the author, Dr. Hubbard.

Dr. William David Bizzell, one of the Faculty of the Southern Medical College, died at Norcross, Ga., June 30th. Dr. Bizzell was born May 31, 1850, in Greene County, Ala., and was the son of James C. Bizzell. He was educated in the common schools, and graduated at the Medical College of Alabama in 1873, taking the Nott medal. He was a member of the Alabama State Medical Association and a counsellor of that body since 1873. He served as Demonstrator in Anatomy at the Medical College of Alabama and also as County Physician. At various times he contributed valuable papers to medical journals, the best known and most important of which was an article on "Climate of the United States Considered with Reference to Pneumonia and Consumption."

An Epidemic of Typhoid Fever occurred recently at Waterbury, Conn. Forty persons were infected from a dairy farm in the neighborhood.

Surgeon Parke has been lionized in London to a great extent and apparently with great justice. Mr. Parke is a modest young man, and has not figured in medicine heretofore; but Stanley gave him most kindly and generous acknowledgments, and Lieutenant Stairs said that Surgeon Parke had saved the life of every white man in the expedition, and had saved the life of Stanley twice. It is gratifying to find that medical services are so highly and justly appreciated. A dinner was given to Mr. Parke on June 6th, at which Sir Andrew Clark presided, and Surgeon Parke was so overwhelmed with compliments that for a time he was too embarrassed to speak. The editors of *The Lancet* have presented Mr. Parke with a massive silver salver.

Dr. Frederick Haud, of Morris, Ill., died on June 14th, aged seventy-four. He was the oldest and the most widely known and distinguished physician in the county.

When Judges Differ.—It has often been pointed out that though the phrase "doctors differ" is so commonly quoted as a reproach to the medical profession, it is one which, both in its origin and its true application, refers at least as much, if not more, to experts in the law, engineering, and in other so-called exact sciences. The Lord Chancellor (Lord Halsbury), speaking at the Mansion House not long ago, went so far as to make it a particular merit of the judges, and one of their claims to the public esteem which they so justly enjoy, "that they spent nearly half their time in differing from their learned brethren."—*British Medical Journal.*

The State Charities Record is the name of an authorized periodical of the State Charities Aid Association of New York, edited by a committee appointed by the Board of Managers. It is published monthly during nine months of the year.

The Virginia Examining Board.—Dr. R. A. Lewis has resigned from the Virginia State Board of Medical Examiners, and gives as his reason the laxity of the members in their work, and failure to adhere to the standard they had adopted. He states, in a letter to the *Southern Clinic*, that the applicants are required to answer seventy-five per cent. of all questions satisfactorily; and a failure to answer thirty-three and one-third per cent. on any one section shall cause the applicant's rejection. But one candidate failed to answer seventy-five per cent., and received only twenty-four on one branch, and was nevertheless passed, every member but Dr. Lewis voting for the candidate. Dr. Lewis very justly remarks that the proper object of sympathy is the future patient of the incompetent practitioner; and that sympathy for an ignorant applicant is misplaced.—*Medical Times and Register.*

The Result of the Burning of an Insane Asylum.—It has now, says the *Montreal Medical Journal*, been authoritatively ascertained that nearly one hundred persons—mostly women—lost their lives in the dreadful holocaust at the Longue Pointe Asylum. In addition to these, a large, but uncertain, number of the patients have since died in consequence of the exposure and hardships.

Dr. von Nussbaum, the distinguished Professor of Surgery, theoretical and clinical, in the University of Munich, having, at his own request, been relieved on grounds of health from the special work of the clinical ward and operating theatre, has received the Order of Merit of St. Michael of the Second Class, in recognition of his services as a teacher and man of science.

Dr. Ottmar Angerer has been promoted Ordinary Professor of Surgery in the Medical Faculty of the University of Munich, and Interim Lecturer and Operator in Clinical Surgery.

Dr. Henry H. Longstreet, one of the oldest and most prominent physicians in Burlington County, N. J., died at his home in Bordentown last week, aged seventy-one years. He graduated from the College of Physicians and Surgeons in 1842, and had been engaged in the practice of medicine nearly half a century.

The Dispensary System in Florence, Italy.—Florence, celebrated for her organization of the "Misericordia"—a Society for the gratuitous assistance of families visited by sickness or death—has supplemented that time-honored institution by another called "La Guardia Permanente Medico-Chirurgica." Every Florentine citizen, male or female, whose circumstances do not admit of paid medical consultations, may now, at any hour of the day or night, by calling at or sending to the headquarters of the "Guardia," in the Via Sole, secure immediate assistance for any injury or disease from which he or she may be suffering.

Protection of the Insane against Fire.—In view of the frightful loss of life from the burning of asylums at Montreal, Canada, and Utica, N. Y., the Committee of Charities of the Massachusetts Assembly has framed a bill requiring iron fire-escapes to be constructed on the outside of all asylums for the insane throughout the State. The New York Lunacy Commissioners have also promulgated regarding this subject.

"Oristry."—According to the *Boston Medical and Surgical Journal*, Dr. J. L. Williams, of Boston, proposes the adoption of this term to signify the rapidly widening specialty of the dental and oral surgeon. The word is compounded of the initial part of *oral* and the terminal part of *dentistry*.

Central Wisconsin Medical Society.—At the annual meeting of this society, held in Madison on June 24th, the following officers were elected: *President*, Dr. Julius Noer; *First Vice-President*, Dr. C. R. Greene; *Second Vice-President*, Dr. J. A. Mack; *Secretary* and *Treasurer*, Dr. C. S. Sheldon; *Censors*, Drs. H. B. Favill, C. A. Gill, and Dr. Bancroft.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, held at Philadelphia, Pa., June 4, 5, and 6, 1890.

E. C. SPITZKA, M.D., PRESIDENT, IN THE CHAIR.

THE Sixteenth Annual Meeting of the American Neurological Association was held in the hall of the College of Physicians, Philadelphia.

The president, on calling the meeting to order for the business of the opening session, said that though there might have been in the history of the society a period when it had devolved upon the presiding officer to fill gaps in the programme, this was no longer the case. With such a plethora of scientific papers as confronted them communications by the president might well at this stage be omitted. He should like to thank the local Neurological Society for its courtesy and exertions on behalf of the National body and he would call attention to a very beautiful specimen of multiple thrombi of the circle of Willis prepared for their inspection. The patient from whom this was taken had been attacked by incomplete left hemiplegia. The facial portion had remained stationary while the rest had improved. Then there had been another attack, involving the other side, with paræsthesia and pain. The case had terminated in coma and death soon after the second seizure.

Unusual Forms of Chorea, Possibly of Spinal Origin.—This was the title of a joint communication by DR. S. WEIR MITCHELL and DR. C. W. BURR.

The first case described was one of inherited congenital chorea, possibly involving the spinal cord. The patient, a young man, eighteen years of age, had presented himself at Dr. Mitchell's clinic in 1889, complaining of constant involuntary movements of the legs, arms, and head. The history of the patient's family was of special interest in this case. His maternal grandmother had suffered from chorea for many years, not from birth, but she had while so affected given birth to the patient's mother, who was choreic from birth till death. Both the patient's parents had died of phthisis. There was no history of other cases of chorea or any nervous disease in the family. The patient's choreic movements had begun in early infancy, probably from birth. As a child he was puny and of tardy development. His present condition was that of a fairly built young man, of good strength, weighing one hundred and thirty pounds. Other than the condition immediately associated with the chorea there was no physiological disturbance. The knee jerk was increased on both sides and the cremasteric, sole, and abdominal reflexes were marked. Ankle clonus was occasionally present and at times rigidity at the knee, the feet being then turned inward at the ankle. All the conditions were increased by emotion and the administration of moderate doses of strychnia. Sensation to touch, pain, and temperature were normal. While awake, the patient's entire voluntary muscular system was more or less in action. The sudden presence of a stranger emphasized the trouble. During sleep there was perfect quiet. No spinal tenderness existed, urine was normal and so, with some slight muscular insufficiency excepted, was vision.

Dr. Mitchell then read in detail two other cases, in which the patients were brothers, their father having, at forty-five years of age, developed alleged choreic symptoms. The first of these two cases had resembled in general aspect canine chorea.

The authors of the paper thought the first of the series of three cases, in which the disease had been through three generations, extremely rare, and that organic changes were present somewhere in the motor tract of the patient might, they thought, be admitted, because of the extreme chronicity of the affection, its resistance to all treatment, and the presence of very distinct ankle clonus and rigidity, these latter symptoms pointing to involvement of the cord. Whether the changes were confined to the cord it was more difficult to say. It was not wished to do more than indicate the spine as possibly implicated in all the cases.

DR. C. L. DANA said he thought the view taken by Dr. Mitchell, as to the relation of heredity in chorea, was the correct one.

DR. SACHS suggested that some of the features Dr. Mitchell had mentioned in detailing his cases of chorea resembled somewhat the peculiar disorders of movement noticed in children with spastic palsies. Some of these conditions made their appearance at a late date and might be either mild or severe in character.

DR. MITCHELL said the view he had advanced was rather an hypothesis than a theory.

DR. SACHS said that he had seen these peculiar disorders present after every trace of the early paralysis had disappeared. In two of the cases cited the patient had shown exaggerated reflexes which were also found in the congenital case, it was possible that one or other of the cases might be congenital palsy, in which the symptoms of palsy had disappeared. He could not abandon the idea that some of the cases described might show changes in some part of the brain.

DR. E. D. FISHER stated that he had seen a great many such cases as Dr. Sachs had referred to. In the almshouse they had both adults and children whose history was that of congenital paraplegia or hemiplegia of cerebral origin, and in which the paralyses were associated with well-marked choreic movements. It had seemed to the speaker that many of these cases where the condition had remained chronic for so long a time were really not of the nature of ordinary chorea, which was a self-limited disease. He had always regarded these conditions as associated with sclerosis, leading to degeneration in the nerve-cells and nerve-fibres, and to descending degeneration in the cord. He had looked upon this as of cerebral origin because it was found that the mental powers, though not greatly affected, showed some dulness, especially in the acquisition of knowledge.

DR. F. X. DERCUM thought it was not at all improbable that a spinal centre might be affected. No doubt there was a form which was purely spinal.

DR. WEIR MITCHELL said that many years ago he had stated his belief that ordinary chorea should be classified into three distinct groups. It was true that cerebral changes could arise in these choreic conditions, but it was rare to see these conditions affecting both sides, no matter what the changes were in the brain. It was especially rare to see the trouble in both lower extremities. Therefore the first case alluded to was not chorea resulting originally from paralytic conditions accompanied by descending degeneration of the cord.

Double Consciousness.—Dr. Mitchell then alluded to the notorious case of Ansell Brown, who had left his home, assumed another name, and, as asserted, had lived for some time without knowledge of his previous existence. On regaining control of his proper identity he had returned home. Hypnotism had been recently tried upon him, and while under its influence the man's mind could be made to revert to incidents in his fictitious existence, while of his real identity he would then know nothing.

DR. C. K. MILLS had seen a number of epileptic cures in which there had existed in the patient a change of ideas as to personality.

DR. R. PARSONS thought the subject was of great importance from a medico legal stand-point as the condition of changed consciousness might be urged in extenuation for the commission of crime.

DR. C. L. DANA said that some years ago he had occasion to go over the literature of the subject. The trouble was very much allied to epilepsy, and the result of his study led him to think that there were gradations of the disease, and that many of these cases were epileptics.

Dr. Knapp cited a case of hystero-epilepsy, in which there were decided spells of changed consciousness. As to the question of spinal chorea he was struck with the analogy of Sydenham's chorea with the conditions of ataxia, tonic spasm, and associated movements, of which he had recorded several cases, and to which some of these cases of chorea bore striking resemblances. It did not seem, however, that we were yet in a position to assume any one of these motor disturbances as having focal significance. They might have their origin anywhere within the motor tract, and he hoped to show that tumors were not unfrequently the cause.

The Weather in Relation to Neuralgic Pain.—Dr. Mitchell had had an intelligent patient, who was a great sufferer from neuralgic attacks; he had made elaborate studies and observations of the effect of variations of the weather upon the paroxysms. Briefly stated, the scientific findings were that the maximum of pain bore direct proportion to the prevalence of storms, and that the aurora was a certain precursor of neuralgic exacerbation.

Chronic Softening of the Cord; Senile Paraplegia.—Dr. C. L. Dana, of New York, read a paper on this subject, narrating a case which, he said, established upon a firm foundation for the first time the fact that in the gray matter of the cord there might exist progressive softening from obliterating arteritis, just as found in the brain. It also established the pathology of senile paraplegia, no convincing evidence as to the nature of which had until recently been adduced. The question of non-inflammatory softening of the cord had been but obscurely dealt with, or let entirely alone. Acute softening had been described usually as synonymous with acute myelitis, but the term was wrongly used and should not be applied to inflammatory processes at all. It had of late been suggested that some of the cases of acute myelitis were in fact primarily necrotic processes, but evidence was lacking in substantiation. The case he would describe did not belong to the acute type but was a chronic myelomalacia of a systematic character.

The patient, an old man seventy years of age, of whose early life little could be elicited, except that he had been generally healthy, had about four years ago noticed some weakness of the legs. There was no pain. The condition had progressed until one year ago there was complete disability to walk, incontinence of urine, and trouble with the rectal sphincters. When seen in 1889 the man had presented the characteristic appearance of senility.

The symptoms of the disease were limited to the lower extremities, which were wasted and contracted, and knee jerks were gone; there was also no clonus or trepidation. Sensation was everywhere normal, indeed, the condition was rather that of hyperæsthesia. No pains in the legs, girdle pains, or bed-sores. Up to the time of the patient's death, which had resulted immediately from exhaustion, the general symptoms had changed but little. The mind was clear, though senile. The only gross changes in the cord or membranes was noticed in the anterior horns in the sections taken low down. The more minute examination of microscopical sections had demonstrated the case as one of degenerative endarteritis with sclerosis, obliteration of the vessels causing the softening of the anterior horns and intermediate gray matter. This process was accompanied by secondary congestion, dilatation of small vessels and capillaries, but no hemorrhages. The condition was one of softening of the cord, precisely analogous to the so-called softening of the brain. It was not inflammatory and could not be termed an anterior polio-myelitis. It was not a cell atrophy and did not belong to the spinal forms of progressive muscular atrophy. While the change was without doubt largely a senile one, the cord did not correspond to the description of such conditions given by Leyden. The disease might, the speaker thought, be called a senile paraplegia from softening of the anterior horns due to obliterating arteritis.

Traumatic Neuropsychoses.—Dr. G. L. Walton read a contribution to this subject in which he dealt exhaustively with the questions of pathology and prognosis in injuries inflicted upon the nervous system by railway collisions and similar accidents. From the influence of Erichsen's views functional and organic injuries were for a long time indiscriminately classed together under the ambiguous and misleading term spinal concussion, while a common prognosis was given to all, leaving the student in doubt as to whether the worst or the best results might be anticipated. To H. W. Page was due the credit of having elaborately corrected this inaccuracy and of sifting out the comparatively rare cases of organic spinal disease, whose sad course and prognosis had been so long allowed to overshadow and include the more common cases in which no demonstrable lesion existed. To the latter class he had first applied the term traumatic neurasthenia. Dr. Putnam, in 1883, after reporting several cases of traumatic hemianæsthesia, called attention to the importance of looking for evidences of typical hysteria in the chronic as well as in the acute stages of so-called spinal concussion. Among those who had early inclined toward the modified views regarding the effects of trauma on the nervous system might be mentioned Dr. Dana, who, writing in 1883, had very appropriately added hypochondria to the two terms already applied. Spitzka had considered that spinal concussion could produce spinal irritation. These theories were in direct opposition to the idea advanced by Westphal, that a diffuse sclerosis was set up by the jar. This view had many followers, both in Germany and America. In a recent work by Clevenger, of Chicago, it was proposed to give to these cases the name "Erichsen's disease." This writer had regarded the spinal sympathetic system as the starting-point of the pathological process. Seguin, in Sajous' *Annual* of 1889, considered organic injury to the nervous system a rarity as resulting from the forms of trauma under consideration. Without exhausting the literature of the subject, it might fairly be concluded that there was at present a very general, though not unanimous tendency to abandon the theory of spinal concussion, and to regard the majority of the genuine cases as identical with already recognized functional forms of disease, rather than cases of organic spinal injury. Dr. Walton's experience had led him from the first to regard disease of the spinal cord resulting from trauma as of comparative rarity, when no dislocation or fracture had occurred, while Seguin's conclusion regarding the preponderance of subjective symptoms, and the degree in which we were generally dependent on the patients, were fully justified by the majority of the cases which had come under the writer's observation.

The President regretted that the two works dealing with this subject were open to the stigma of having been written for trade purposes. It was important in discussing the question to avoid anything but its clinical aspect.

Dr. P. C. Knapp could not agree with the author of the paper in the position he had taken. Page had deliberately ignored most important neurological points. The theory of Charcot that many of these cases were hysterical was pretty well exploded.

Dr. Putnam thought there were but few persons who could carry out successfully a system of deception during a long and searching examination, much less through two such investigations.

Dr. F. X. Dercum said that in his opinion there was a union of two factors. In some cases there existed actual cause for painful back. It was remarkable how the same story would be repeated unsolicited. It required a person well trained in the subject to relate such symptoms. Then there would be diminution of the heart-beat, great awkwardness of movement, marked disorders of sensation, errors in treating points of contact, and many other mistakes which a healthy man could not make. Many of these symptoms were such as the patients could hardly pick out for themselves. It was immaterial

whether the initial trouble was actual organic disease or profound functional disturbance, the fact remained that these people did not recover.

Dr. W. R. Birdsall agreed that it was the most conservative view to say that there was possibly a traumatic lesion in a certain number of these cases, still he thought the great majority showed functional phases. The chief element in the production of these conditions, even if there existed organic changes in addition to the functional disturbance, was emotion, and psychic shock.

Dr. D. Inglis did not agree with the author of the paper. The profession had to take one position or the other in deciding whether these cases were organic or functional, and then a jury might do as it thought fit. He also proposed a method for testing hypersensitive areas.

Dr. C. K. Mills thought there were at least three classes of cases resulting from injury: 1, Pure fright; 2, cases in which the indications were clear that fracture or hemorrhage or other serious lesion had taken place; 3, cases in which the symptoms presented were both objective and subjective, with a preponderance of the latter. He thought that the existence of some organic lesion, whether myelitis or the result of hemorrhagic pressure upon some delicate part of the nervous system, would explain many of the symptoms peculiar to this class.

Case of Complete Paraplegia Cured by Trephining.—Dr. F. X. Dercum presented a patient upon whom trephining of the upper dorsal vertebral arches, for paraplegia and complete paralysis of the sphincters, had been performed, resulting in complete recovery.

The President, in commenting on this unique case, characterized it as almost unprecedented.

Dr. Putnam said the case seemed to be one of unusual interest, and thought that they must all welcome such advance in the surgery of this region. The speaker reported several cases in which he thought exploratory operation might have been done with benefit.

Dr. V. P. Gibney said he was extremely delighted with the brilliant results in this case. From the way the patient now held his head he should be inclined to look upon the case as an old Pott's disease. Surgeons had been chary of operations in these cases though the operation was comparatively an easy one, at least simple in detail, and with the aseptic and antiseptic methods of to-day it was practically impossible to have bad results, and recovery was to be expected.

The President said they would be glad to know to what extent the present position of the head corresponded with the position before the operation.

Dr. Dercum said the position was at that time normal. He considered the present inclination of the head forward as due to loss of certain attachments of the trapezius muscles at their points of insertion into the spinous processes. There might have been a rheumatic element in this case affecting the meninges of the cord.

The President said he would like to ask Dr. Gibney as to the deformity in which there was extreme bending forward of the neck.

Dr. Gibney said this condition sometimes obtained to an indefinite extent. It might be a senile kyphosis. Though it would perhaps be urged that Pott's disease at such an age was impossible, yet as a matter of fact there were quite a number in whom it developed after fifty or sixty, following a fall or injury. The position of this man's head might be due to loss of substance of the bodies of the vertebræ.

Dr. W. M. Bullard thought the rapid advance in spinal surgery should lead to more definite conclusions as to the cases of Pott's disease suitable for operation.

Dr. B. Sachs said he was gratified to hear the report of such a case as Dr. Dercum had presented. It went to show that many of the cases hitherto operated upon had been badly chosen. When cases could be selected, statistics would probably be more encouraging and favorable.

The President thought that the theory of rheumatism in this case could not be entirely disposed of.

Dr. C. L. Dana said he did not share the optimistic views which Dr. Putnam had advanced, and should be sorry to start a boom in spinal surgery. If the history of all the operations already performed in this field was known he thought they would be disposed to follow the conservative suggestions of Dr. Sachs, and would deal only with selected cases.

Dr. Gibney said that he did not by any means desire to start a boom in spinal surgery. What he had meant by an easy operation was that in these old cases of Pott's disease the spinous processes were very prominent, and the soft parts were thin and readily got at. Cases should always be very carefully selected.

Dr. Dercum thought that the proper cases were difficult of selection, and it was only now and then that success could be hoped for. He regarded the results in his case as fortuitous.

A Case of Locomotor Ataxia Associated with Nuclear Cranial Nerve Palsies and with Muscular Atrophies.—Dr. Frederick Peterson reported the history of the above-named case. The patient had been under the writer's observation since March, 1890, but the features of the case had been previously described by Dr. Seguin, in the *Journal of Nervous and Mental Disease* for May, 1888. It was the first of five cases of ophthalmoplegia reported by that author. As there had been so many new developments in the patient's condition during the past four years it was thought best to briefly outline the history from the first observations made up to the time when he came under the writer's notice. Mr. J. T——, now thirty-seven years of age, had had a chancre and secondary symptoms fifteen years ago. In 1882 he had discovered one morning dimness of vision and external strabismus of the left eye, with diplopia. A little later he had shooting pains in the legs, occasionally in the arms. In 1883 he had a momentary loss of consciousness, and fell, cutting his head. His left testicle also became swollen and hard during this year, and he was under specific treatment at Hot Springs for some time. In 1884 he had partial double ptosis. In the right eye, the internal rectus, inferior oblique, and sphincter iridis were paralyzed, and the superior and inferior recti feeble. The other muscles were normal. In the left eye the muscles supplied by the third nerve acted variably and feebly. The other muscles were normal. Both pupils were completely motionless to light and accommodation, the left larger than the right. Ophthalmological examination resulted as follows: R. V. $= \frac{20}{40} : \frac{20}{40}$ W $+ \frac{1}{18}$; L. V. $= \frac{20}{30} : \frac{20}{40}$ W $+ \frac{1}{18}$. R. A. $= \frac{1}{10}$; L.A. $= \frac{1}{14}$. There was no lesion of the optic nerves. The left cheek was a little inactive and there was a mild paresis of the right hand. Dynamometer, R. = 42 to 44; L. = 45. No Romberg symptom. Knee-jerks exaggerated. Both feeble and involuntary micturition. In 1885 the ptosis was nearly total on the left, but partial on the right side. In the right eye the condition of the muscles had remained unchanged, while in the left they had improved so much that they acted almost normally. Some paresis and atrophy of both temporal and both masseter muscles was now noted. In 1886, when lost sight of by Dr. Seguin, the ptosis was a little greater, the bladder still paretic, and the masticatory muscles unchanged. No marked facial paresis. The knee-jerks, previously exaggerated, had fallen to about normal. Dr. Seguin, writing in 1888, had said of this case that some of the symptoms seemed to justify a suspicion of incipient "posterior spinal sclerosis."

Since 1886 until the present time there had been gradual progress in the disease, and the present condition of the eyes were as follows: In the right all of the muscles, external and internal, except the rectus externus, were completely paralyzed. The rectus externus was paretic and when moved exhibited clonic spasm. In the left eye there was almost complete ophthalmoplegia externa et interna. Both pupils were widely dilated, equal, and immobile. Divergent squint of right eye. Vision was

unchanged. As far, therefore, as the innervation of the ocular musculature was concerned we had now lesions affecting both third nerves, both fourth nerves, and both sixth nerves. The weakness and atrophy of the masseter and temporal muscles was more pronounced. These muscles did not react to faradism. There was no anæsthesia of the face. The tongue deviated slightly toward the left. The electrical reactions in the face and tongue muscles were normal. There was still some evidence of weakness in the right hand. The patient had now well-marked tabes dorsalis. There was marked ataxia of all four extremities. He could not walk without assistance. The knee-jerks had disappeared. There was numbness, anæsthesia, and analgesia in all of his fingers. In both legs as far as the knees there was almost complete tactile anæsthesia. Muscular sense was entirely lost in both feet. In addition to other symptoms, which pointed out fully developed locomotor ataxia, the patient presented some very interesting trophic disturbances. Besides that of the muscles supplied by the motor branches of the trigemini already described, there was wasting of the right trapezius with a degenerative reaction. In the left upper extremity there was complete paralysis of the two long extensors of the phalanges of the thumb, and atrophy and paresis of the abductor minimi digiti and of all of the interossei and lumbricales, with degenerative reaction. On the right side there was almost complete atrophy of the opponens and abductor pollicis. Considerable wasting was apparent in the adductors of both thighs, more upon the right side. The main features of the case might be summarized as follows: The patient had had a number of bilateral motor cranial palsies, namely, the third, fourth, fifth, and sixth nerves. He had also exhibited slight traces of crossed paralysis for more than four years. Locomotor ataxia had developed, as was shown by the occurrence at one time of lightning pains and by the presence now of ataxia, widely distributed anæsthesias, failure of knee-jerks, and ocular, vesical, and anal symptoms. Finally he presented marked trophic changes in numerous muscles. As to the morbid processes underlying these various manifestations, there was, in the first place, undoubtedly a sclerosis of the posterior columns of the spinal cord. The ophthalmoplegia was of course nuclear. Read in one way the symptoms on the side of the cranial nerves, taken in conjunction with the muscular atrophies and paralyses elsewhere, certainly very closely resembled the syndrome so well described by Dr. Sachs in a paper last year under the title of "Polioencephalitis Superior and Poliomyelitis." The most important matter to be settled in this case was whether the muscular atrophies were due to peripheral or central lesions. Speculation upon the question would seem to be of very little utility, and its solution must be left to the hoped for autopsy. It had been assumed by a number of authors that total paralysis of all of the muscles supplied by the third nerve implied not a nuclear but a nerve-trunk palsy. In the writer's case all of the muscles of both third nerves were totally paralyzed, including both irides, and yet there was every reason to believe that the palsies were nuclear. It would at least be difficult to conceive of a lesion at the base of the brain so widely affecting the trunks of both third, fourth, and sixth nerves, and the motor portions of both trigemini, yet permitting the escape of the sensory portions of the latter.

DR. C. K. MILLS thought that the case might be some peculiar irregular form of syringo-myelia.

DR. E. D. FISHER suggested that the case was one of amyotrophic lateral sclerosis.

DR. SACHS thought the case very closely resembled one of his, in which the diagnosis was polio-encephalitis superior and poliomyelitis, although there were more symptoms of tabes dorsalis than in his case.

DR. PETERSON did not think the case one of syringomyelia, owing to the very symmetrical distribution of the nuclear palsies and because there was no anæsthesia of the upper extremities, face, or trunk.

Multiple Neuritis, or Beri-Beri, among Seamen.—DR. J. J. PUTNAM reported about twenty cases of a disease resembling beri-beri, but possibly another form of multiple neuritis, occurring among fishermen in northern latitudes, and referred to a similar series of cases reported by Dr. F. C. Shattuck in 1881. By correspondence with physicians in the seaport towns Dr. Putnam had ascertained that, besides the larger epidemics, sporadic cases occurred from time to time. One physician had reported frequent cases of swelling and numbness of the hands, attributed to handling fish. The influence of alcohol and the metallic poisons could be excluded, and since the outbreak occurred only now and then the influences to which the seamen were habitually exposed could hardly be considered as the whole cause, though insufficient food had seemed to play a part in some instances. Most of the patients had recovered, but some had died.

DR. GRAY asked if these men carried large quantities of ice, because he had seen neuritis following the handling of ice, which promptly subsided if this cause was removed.

DR. BIRDSALL asked as to the amount of air supplied to the hold of these vessels, and to the seamen's quarters. Cases recently reported to him had led to the impression that the men who had died had been specially exposed to bad air in the hold, while those in good quarters had escaped. He agreed also that cold was an important element in the production of nearly all forms of neuritis.

DR. HUNTER asked whether the men's diet had been of fish.

DR. PUTNAM said that fish had not been the diet, but salt pork, sometimes fresh vegetables and fresh meat. But in one of the worst cases it had been salt pork.

On Cases of Postero-lateral Sclerosis, with Special Reference to the Pathology of the Disease.—DR. JAMES J. PUTNAM referred to a series of eight cases of similar character, presenting the symptoms of "combined sclerosis" of the spinal cord, which he had seen during the last few years, and reported four of them in which he had examined the cord microscopically. All the cases of the series, though differing in some respects, resembled each other as follows: All the patients were past middle life; all were either anæmic or in a state of poor nutrition. The symptoms in all had consisted in both motor and sensory disorders in all four limbs, sometimes associated with incoördination, sometimes not. The knee jerk was exaggerated in all but two or three; in those it was absent. Tabetic pains were present in one case only. Anatomically sclerosis was found in the posterior and lateral column, varying in exact position. In almost every case the posterior change had seemed the older and most intense. Besides the "typical" sclerosis, there was evidence of a more recent process, characterized by granule-cell formation, and the breaking down of the nerve-tubes so as to form circular or oval spaces. This new process was developed on the borders of the older change. The gray matter of the cord was more or less affected, and the nerve-roots in about the same degree. The cases had all run a rapid course, terminating, after one to four years, in death, preceded by paraplegia, due to non-inflammatory softening. Next to inherent structural weakness, as an etiological factor, came impaired nutrition and toxic influences. The importance was pointed out of recognizing and attempting to meet the partial courses of the disease, of which several might be present at once. As special stigmata of degeneracy in these four cases the writer referred to the mental condition and family history of several of the patients; to the remarkably abnormal shape of the cord in one; the small size of the dorsal gray matter in another, and the presence of a second central canal in a third.

DR. S. G. WEBBER cited the case of a young girl who, from excessive walking, had developed decided symptoms of lateral sclerosis. This patient had gradually recovered the use of her limbs.

DR. PUTNAM, replying to Dr. Dercum, said that there

had been no serious involvement of the internal organs in any of the cases, and no typical Bright's symptoms. These patients were so largely women that he could not but assume the existence of some lesion from impaired nutrition and constitutional taint.

On Ingravescent Apoplexy.—Dr. C. L. Dana read a paper with this title. He said that there were three sets of intracranial blood-vessels, those in the dura, those in the pia-mater, and those in the substance of the brain. We had correspondingly three types of intracranial hemorrhage. The central hemorrhages were far the most common, and presented a tolerably uniform clinical type. There was one form, however, which seemed to have escaped critical attention, though it could not be excessively rare. In 1876 Dr. Broadbent had reported six cases of what he had termed "ingravescent apoplexy." In 1889 M. P. Puesch, of Montpellier, had also reported a case of the same character. The writer had met two cases presenting the general clinical characters of ingravescent apoplexy, but was able to make an autopsy upon only one, of which the data was as follows: A woman was brought to the hospital May 1st, without any history. She was in a stupid condition but not unconscious, and she was at first thought to be intoxicated. Examination showed, however, some hemianalgesia of the left side and slight hemiplegia of the same side. The right pupil was slightly contracted, temperature normal, pulse tense. Next day the patient's mind was clearer; she answered questions and recognized those about her. But the hemiplegia was very much worse, and the analgesia no better. Toward night she became more stupid and finally comatose; œdema of the lungs developed. No contracture of the paralyzed side was noted. The temperature rose and the patient died next day, May 3d. At the autopsy the brain was found congested. Pressure over the supramarginal gyrus showed that there was a softened place beneath it. The brain was placed in boroglycerine and alcohol, and opened later by a vertical section. These showed a clot in the lateral ventricle and some blood in the third ventricle. Beneath the supramarginal gyrus was a large hemorrhagic focus about an inch and a half in diameter. This extended forward and downward, cleaving the external capsule. The hemorrhage had finally extended downward and inward, and broken into the lateral ventricle. Puesch had attempted, on the slender basis of seven cases, to erect "ingravescent," or, as he called it, "progressive" apoplexy, into a distinct type. This seemed to the author to be somewhat premature. The history of his case was not exactly like those of Broadbent's in respect to retention of consciousness, and the hemiplegia was relatively less marked. Yet anatomically it was one of the "cleaving" hemorrhages due to rupture of a posterior branch of a lenticular artery, and running the same course as was described by Broadbent. The hemianæsthesia seemed to the author to be a very distinctive point. Practically the question came up as to whether in such cases trephining would be justifiable. In general, the idea of trephining for non-traumatic hemorrhage was not to be entertained at all, but in ingravescent apoplexy it deserved consideration, because here the hemorrhage was accessible, and because, unless some relief was given, it would surely break into the lateral ventricle and kill the patient. In all the reported cases, also, the patients were not old, were not syphilitic, and presumably had not extensively diseased arteries. In reaching hemorrhages in these cases, the best place to trephine would be a little below and in front of the parietal eminence. The surgeon should then explore downward and forward, care being taken not to injure the terminal branches of the Sylvian artery, which were in this neighborhood. In cases of "ingravescent" apoplexy surgical interference, if undertaken, must be before the blood broke into the ventricles. This could be told by the sudden increase in the severity of the symptoms, and if the blood was poured in rapidly by contractures on the paralyzed side. The temperature changes were believed to be the same in the ingravescent as in ordinary apoplexy. The author trusted that the report of his case might excite the interest of others, and call attention to this apparently distinctive and fatal form of cerebral hemorrhage.

Dr. Mills had seen a number of such cases. The result of his experiments as to the best method for operative interference had led him to think that the trephining, if done at all, should be several inches back from the temporal lobe, along the junction of the second and third temporal convulutions. He had known of patients with intraventricular hemorrhage recovering independent of the question of trephining.

Dr. W. Sinkler said Dr. Dana had referred to the question of temperature. He had recently had a patient die from enormous hemorrhage into the ventricle and the temperature at death was 108°F.

Dr. Webber questioned the utility of trephining in these cases in which the history was rupture.

Dr. Mills said the advantage of trephining was that it gave the patients a lease of two or three weeks, as the breaking into the ventricles did not take place until late. By trephining and finding the bleeding-point there was a chance of controlling it.

Dr. Dana said that trephining was purely empirical, and he could not say whether it was good or not.

Pons Lesions in their Relation to Associated Eye Movement; Paralysis. — Dr. Spitzka presented this paper by title, accompanied by the demonstration of a specimen of a minute focal lesion of the dorso-caudal part of the pons, unilaterally situated in and near the abducens nidus. In connection therewith Dr. Putnam mentioned one of similar location to Dr. Spitzka's, in that the presumable lesion, for the patient recovered, must have occupied the same position.

A Contribution to the Pathology of Solitary Tubercle of the Spinal Cord.—Dr. Heuter read the above paper. It consisted of a report on the clinical history and pathological anatomy of three hitherto unpublished cases of solitary tubercle of the cord, and of a brief analysis of the clinical and pathological features of the condition based on these cases, and on those which had been collected from the literature on the subject. It was believed that the clinical history of solitary tubercle of the cord could be more accurately written than heretofore with the help of the facts that had been recorded in the given cases. The uniformity of the symptoms in different cases, especially as regards their course, the rapidity with which the usually unilateral symptoms became bilateral, the comparative insignificance of the irritative phenomena, and the frequency with which the signs of tubercular disease in other organs existed, were characters of solitary tubercle of the cord which might help in this distinction, both from tumor of the membranes and from other varieties of tumor of the cord.

Dr. Sachs said it was some years since his paper on this subject was written. At that time he had thought that the very slow development, the strictly unilateral symptoms and subsequent spread of the disease, involving both halves, would constitute a basis for diagnosis of tumor of the cord. Now the point came up with regard to the possibility of distinguishing between extra- and intradural tumors.

Demonstration of Some Special Anatomical Characteristics in the Brain of a Distinguished Scientist.—Dr. B. J. Wilder presented the brain of the late Mr. Chauncey Wright, and demonstrated to the Association what he deemed striking anatomical points. One peculiarity specially dwelt upon was the existence of a very simple insula instead of a complex one. Then the inhibition of the fissure of Rolando by an isthmus was so rare as to call for attention. Then, in contradistinction to the condition in other brains, it would be seen that the central fissure above that point was shallow. The speaker urged his hearers to aid in every way possible the further

investigation of comparative anatomical study in this field. To successfully effect this, it was necessary to secure young human and apes' brains in every stage of development.

Tumor of the Quadrigeminal Region, with Special Reference to Ocular Symptoms.—Dr. B. Sachs read a paper with this title. He had been fortunate enough to obtain two autopsies, during the past year, which bore upon this question, and also several cases which were subjected to careful clinical examination. His first case was one of unusually severe tuberculosis cerebri. The main points of the history, which he had been able to complete through the kindness of several colleagues, were these: E. L——, aged three years. When first seen she had double ptosis, but no other ocular paralysis was observed. She was dull and listless, and had a pulse that ranged from 145 to 160, but with normal temperature. The mother had noticed a change in the child's disposition since an attack of measles nine months previously. The child did not care to play, but preferred to sit quietly in a chair all day long. She staggered in walking and occasionally fell. She had no epileptic attacks, and had vomited but once. Knee-jerk was absent. The right hand was weaker than the left. No anæsthesia or ataxia. There was paresis of both levator palpebrarum, the pupils being half covered. No nystagmus. Pupils were equal, moderately dilated, and reacted well to light and accommodation. December 28, 1889, the patient had come under Dr. Sachs' care. The condition at that time showed great changes. Examination disclosed double and almost complete ptosis. There was no upward or downward movement of either eye. Both external recti muscles were thrown into clonic spastic condition when the attempt was made to use them. The interni were capable of very slight movement, but all the other ocular muscles were completely paralyzed. The accommodative reflexes were still distinct, and there was slight contractility to light. There was also slight left facial paresis. The vision was very much impaired. Although in a semi-stupor, the child could be made to walk, and then exhibited most distinct cerebellar staggering, walking with a broad base, and almost falling to the right side. The oculist reported plaques of choroidal atrophy below the macula of left eye. The reflexes were exaggerated and there was occipital headache. The diagnosis of tumor of the corpora quadrigemina was given. The tumor was supposed to be associated with a general tubercular meningitis. The child grew rapidly worse, and after passing through several convulsive seizures, becoming blind, and finally developing left hemiplegia, she died February 4, 1889. Autopsy showed the dura adherent to the skull and it had to be removed with the calvarium. The quantity of the sub-dural fluid was slightly increased. A solitary tubercle was at once discovered near the right lateral sinus, pressing into the lateral edge of the cerebellum and producing thrombosis of the lateral sinus. Other tubercles with large areas of softened tissue were found in the cerebellum. Deep examination of the brain showed the hemispheres to be healthy, with the exception of the small tubercular deposits along the paths of the blood-vessels. The cerebellum was the seat of the most profound changes. The base presented several unusual conditions. There was great thickening of the pia, with small tubercular deposits between the corpora mamillaria and optic chiasm, and in the interpeduncular space. The thickening at this point was so great that both third nerves, instead of lying across the crura, after removal of the brain, pointed backward, and the right, the sixth, was twisted out of its position. Section of the brain showed the tumor to occupy almost the centre of the tegmental division of the crus and had left a very small portion of the corpora quadrigemina and the brachi intact. The occipital headaches and the cerebellar staggering were the only symptoms which could be ascribed to the large tubercles in the cerebellum, though both these symptoms might be due to the lesion of the quadrigemina region. It was probable that the sixth and seventh nerve nuclei were responsible for the symptoms pointing to lesions of those nerves, or that the basilar meningitis was at fault. Certain it was that the latter condition was late in developing, for, for months, the symptoms had been distinctly nuclear. In spite of the manifold morbid conditions, it was most remarkable that the ciliary muscles and the sphincter irides had remained exempt during the entire period of observation. Considering the compactness of all cerebral structures in the crura, it would be supposed that there could be no difficulty in making a differential diagnosis between cases of tumor in this region and a chronic inflammatory process.

Crus Lesion.—This was the title of a second paper by Dr. Sachs. Crus lesions were rarer than many other cerebral lesions but their symptoms were well-marked. The case under consideration had some special interest, however, in connection with post-hemiplegic disturbances of motion, and from this point of view the results of the post-mortem examination were worthy of consideration. Seven years ago the patient, a woman about fifty years of age, had had a dizzy attack one morning, and had found her vision rather blurred. There was a recurrence of the attack in fifteen minutes. There was no unconsciousness nor difficulty with speech, but when the patient attempted to walk she found she could not with ease. By morning she had almost complete left hemiplegia, she could not open either eye. At that time speech was heavy and indistinct, but from this she had recovered in three weeks. Hearing, taste, and smell were altogether normal. The hemiplegia was never recovered from, the patient became somewhat unruly and demented, and was finally taken to the Montefiore Home, where she had remained for many years. A few further details of the patient's chronic condition were elicited in examination. There had been no history of syphilis, but there was very marked atheroma of the peripheral arteries. In addition to the left hemiplegia, the patient had suffered amputation of the right leg above the ankle, for old necrosis of the tibia, fully six years before. There was rigidity of the left leg, and increased knee-jerks of both sides. The wrist reflex was decidedly increased on the paralyzed side, but the left upper extremity was subject to the wildest ataxic movements. This would go on until the arm dropped from exhaustion, when it would remain quiet until aroused again by an effort to use the hand. She became extremely emotional, took very little nourishment, and finally died. The diagnosis of crus lesion of the right side, probably softening from thrombosis, was made, and confirmed by the autopsy.

On the Germ of a Communicable Disease Derived from a Dog, Alleged to have Died of Rabies, which Retains Rabic Characters.—Dr. Richard Mollenhauer exhibited some microscopic specimens, taken from a dog which he had succeeded in rendering rabid by inoculation. The germ was a bacillus whose various growth-stages presented a uniform type. In its adult period it was usually found in chains typically made up of four, rarely of three, somewhat more frequently of two, and exceptionally of five links.

Case of Insular Sclerosis in which an Attack of Cerebral Hemorrhage Arrested the Tremor on the Hemiplegic Side.—Dr. Wharton Sinkler related the history of this case. The patient, a man, aged sixty-seven years, had always enjoyed good health until about ten years ago, when he began to notice tremor in both hands, but worse in the left. In 1889 he had experienced an attack of left hemiplegia, without loss of consciousness. Since that attack there had been no tremor on the left side, but a coarse tremor on the right side still persisted. The patient's appetite and general health had remained good, the hemiplegia continued about the same, with no further involvement of the tremor.

Remarks on Therapeutics as Applied to Nervous Disorders.—Dr. W. R. Birdsall read a paper with this title. While admitting that many of the diseases which the

neurologist was called upon to investigate were practically incurable, the author maintained that those who saw no advance in the therapeutics of nervous diseases were probably looking in the wrong direction for progress, the advance being in great part the outcome of those very investigations considered by many as unpractical scientific refinements. The early diagnosis of disease he regarded as the most important factor for therapeutic success in diseases of the nervous system, as it frequently enabled the physician to check the course of a disease where marked disability had not yet resulted. Hygienic measures were considered of prime importance and pharmaceutical remedies as valuable accessories in the treatment of these diseases. All relation between storage and expenditure must be readjusted to the disturbance in equilibrium, and the aim of therapeutics consisted in bringing about such a readjustment. The modern craze for so-called physical culture, the author believed, was bringing forth dangers as great as those it was sought to remedy, through over-training, improper training, training for brain-workers which fatigued rather than rested the brain, together with other faulty methods. Hydrotherapy, he considered, was much neglected, and electrotherapy overestimated. Next to hygiene, cutaneous irritation was decidedly the most important therapeutic measure possessed by the neurologist. Surgical interference and the drugs usually employed by the neurologist were then briefly referred to.

Dr. W. Sinkler believed in the use of drugs in nervous disorders. No doubt arsenic in chorea, hyoscyamine or hyoscine in various tremors, the iodides and antisyphilitic remedies in specific diseases of the nervous system, were all of value. He wished to put himself on record as not being a pessimist or nihilist.

Dr. Brush said he wanted to accentuate what Dr. Birdsall had said as to the management of cases of nervous diseases. A great many could be better treated by other means than drugs. He should some day present some cases of insanity from drug poisoning. Once he used to try everything that came along, but now he made less and less use of drugs.

Dr. L. C. Gray said he was a believer in the efficacy of properly directed therapeutic measures in combination with everything else in the treatment of nervous disorders—chorea in all its minor forms, neuralgias, functional nervous disorders, subacute or acute mental troubles, except acute mania.

The Pathological Findings in Dr. W. A. Hammond's Case of Athetosis.—Dr. G. M. Hammond read a report on the pathological findings in the original case of athetosis on which Dr. W. A. Hammond's description of athetosis was based. After briefly referring to the case in detail Dr. G. M. Hammond stated that the portion involved in the lesion was a lengthy one in the antero-posterior direction, parallel in its short axis with the internal capsule. Its posterior end had invaded the stratum zonale of the thalamus in its posterior half of the internal capsule. In its anterior extension it had crossed the capsule invading the posterior third of the outer articulus. The author called attention to the fact that the motor tract was not implicated in the lesion, and argued that this case was further evidence of his theory, that athetosis was caused by irritation of the thalamus, the striatum, or the cortex, and not by a lesion of the motor tract.

Dr. E. C. Spitzka, reported a case in which the lesion was found to be in the same situation, as in Dr. Hammond's case.

Dr. E. C. Seguin presented a paper on atheto-choreic spasm of the right side of the body. The post-mortem had shown a glioma of the left thalamus opticus and adjacent internal capsule. Dr. Seguin's views were that all cases of athetoid and choreiform movements following hemiplegia were due to lesions involving the thalamus and adjacent capsule.

The officers elected for the ensuing year were: *President*, Dr. Wharton Sinkler, of Philadelphia; *Vice-Presidents*, Dr. C. L. Dana, of New York, and Dr. S. G. Webber, of Boston; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York; *Councillors*, Dr. G. L. Walton, of Boston, and Dr. L. C. Gray, of New York.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CHEMISTRY OF GOUT—THE PUBLIC HEALTH DIPLOMAS OF THE UNIVERSITY OF GLASGOW—THE PROPOSED RECONSTITUTION OF THE UNIVERSITY OF LONDON.

London, June 14, 1890.

At the last meeting of the Medical and Chirurgical Society an important contribution to our knowledge of the chemical changes occurring in the tissues of gouty persons was brought before the Society by Sir William Roberts, in the form of a very elaborate paper on the subject. In bringing forward the subject Sir William Roberts referred to a recent paper of his, in which he had shown that in the physiological state uric acid existed in the blood and urine exclusively as quadrurates, and that when it appeared in any other form this was due to abnormal changes in the quadrurates. In that paper he had traced the changes which the quadrurate underwent in urine—changes leading up to the separation of free uric acid in gravel. In the present paper he proceeded to consider the changes which the quadrurate underwent in the blood—changes leading up to the deposition of free uric acid in gout. These latter changes were intimately connected with the property possessed by the quadrurates of taking up in alkaline solutions an additional atom of base—thereby becoming converted into biurates. A knowledge of this reaction enabled us to present a coherent view of the succession of events which culminated in a gouty paroxysm. Normally, the uric acid, which circulated in in the blood as quadrurate, was at once removed unchanged by the kidneys. But in the gouty state—either from defective kidney action or from some other cause—the quadrurate lingered unduly in the blood; circulating then in a medium rich in sodium carbonate, it was gradually transformed into sodium biurate, which was almost insoluble in blood-serum and probably, for this reason, was difficult of removal by the kidneys. Under these new conditions sodium biurate accumulated more and more in the blood and, when the accumulation reached a certain point, was precipitated in the crystalline form in the joints and elsewhere, thereby determining the occurrence of a fit of the gout. Sir William Roberts said he based this view upon a study of the reactions of blood-serum and synovia with uric acid and the urates. In the case of blood-serum these depended essentially on the saline ingredients; the sodium salts exceeded all the other salts put together in the ratio of 7 to 1, and a solution of 0.5 per cent. of sodium chloride and 0.2 per cent. of sodium carbonate was a fairly exact imitation of blood-serum so far as concerned its saline ingredients. Experimentally, it was found that such a solution behaved with uric acid and the urates in the same manner as blood-serum itself, and in the same manner as a solution composed of all the salines of the serum in their due proportion. The behavior of uric acid and the urates with this "standard solution" was then studied in detail and the results checked, by comparing them with those obtained with blood-serum under similar circumstances. The author found that sodium biurate dissolved in water at 100° F. in the proportion of 1 in 1,100, but that it was almost insoluble in the standard solution and in blood-serum, and no addition of potassium, lithium, or magnesium salts—whether alkaline or neutral—made the slightest difference. The solvent power of the standard solution was found to depend exclusively on the sum of sodium salts contained in it, and the degree of alkalescence had not the least influence; the nearer the standard

solution approached to pure water, the higher became its power of dissolving sodium biurate, and *vice versa*. The solubility of gouty deposits was tested by suspending gouty articulations, encrusted with uratic deposits, in a large volume of blood-serum; the deposits remained unchanged even after immersion for many months. Uric acid, itself, dissolved freely (as a quadrurate) in the standard solution —and also both in blood-serum and synovia—but after an interval of a few hours or a few days it was again precipitated, often somewhat suddenly, in the form of crystalline needles of sodium biurate exactly resembling those found in gouty deposits. The author held that this reaction was analogous to the phenomena of the gouty paroxysm. In gout, he considered that the blood became increasingly charged with uric acid, until, after a certain period of incubation, sudden precipitation of sodium biurate occurred and the "fit" of gout took place; then followed a process of recovery with restoration of the blood to a purer state. In the experimental process a similar succession of events was observed: solution of uric acid in the medium as quadrurate; gradual conversion of quadrurate into biurate (stage of maturation); deposit of the biurate in the crystalline form (stage of precipitation); restoration of the medium to comparative purity. With regard to the conditions which hastened or retarded the processes which culminated in the precipitation of sodium biurate, the following results were arrived at: 1. Precipitation occurred earlier in synovia than in blood-serum. 2. Increased alkalescence of the media favored the stage of solution, but did not retard the stages of maturation and precipitation. 3. The addition of sodium salts hastened maturation and precipitation. 4. The addition of potassium, lithium, or magnesium salts had no effect either way—except potassium chloride, which retarded maturation. 5. Maturation was hastened and precipitation occurred earlier at 100° F. than at the temperature of the room. 6. The proportion of uric acid in solution was the circumstance which exercised the most decisive influence on the speed of maturation, and on the time of advent and copiousness of precipitation. If the proportion of uric acid in solution were 1 in 2,500 or over, there was observed in the middle period of maturation, on the second or third day, a copious critical precipitation; but if the proportion were 1 in 4,000 or under, the precipitation was throughout scanty and gradual, and postponed to the twelfth or fourteenth day. Dr. George Harley remarked that when Sir Alfred Garrod proved that gout was due to the existence of uric acid in the system, a distinct advance in our knowledge was made. A further advance was made when it was shown that an acute attack of gout was due to the deposition of uric acid in the articular cartilages. Later on, it was shown that the deposits were not due to inflammation of the joints, but that the deposits caused the inflammation around the joints which was known as gout. Sir William Roberts' present paper was a contribution to the chemistry of gout, and Dr. Harley urged that, through chemistry, a new pathology would be founded in which all morbid changes would be proved to be due to chemical action. Dr. Haig observed that Sir William Roberts's paper afforded a chemical explanation which he had long wanted. He had found that alkalies increased the excretion of uric acid, and Sir William Roberts had shown that increased alkalescence favored the state of solution of uric acid. Similarly, acids lessened the amount of uric acid excreted. Sir William Roberts then replied, and remarked that he had confined himself to certain chemical results, and had drawn no conclusion as to the profounder theories of gout. There was something in gout beyond the chemistry of the urates; it was, in essence, a mode of nutrition associated with an error, which was uric acid. There was a colloidal form of uric acid, as well as the crystalline form, and the action of the two forms also differed. He believed that if an attack were imminent, a patient ought not to take mineral waters containing soda and lime, except very sparingly at first. Dr. Herman Weber had, for many years, warned his patients on this point. Sir William Roberts said he thought it possible that most of the good done at mineral springs was due to the water taken, and not to the salts it contained.

At the recent session of the General Medical Council one of the burning questions discussed was, as to certain diplomas in public health issued by the University of Glasgow. It appears that the diplomas in question were granted after a very superficial examination, and the Council considered that sufficient proof of knowledge of the subject had not been evinced by the candidates. Ultimately it was decided to refer the documents relating to the matter to the Council of the University of Glasgow, and in the meantime to register no more of the diplomas issued after such an insufficient examination.

The question of the reconstitution of the University of London still lags. The Senate is really between two fires. On the one hand they have to deal with the various and conflicting claims of the various teaching bodies, and also those of the medical examining boards (*i.e.*, the colleges of physicians and surgeons); on the other hand, they must satisfy their own graduates, for Convocation can veto any scheme, though it is powerless otherwise in the present matter. The real point at issue is, whether the standard of the examinations shall be reduced. If it is not, it is difficult to see how the medical schools can be satisfied; if the standard is reduced, the present graduates will be sure to object, and perhaps veto the scheme. In the latter case, a second (teaching) university is almost certain to be established in London, and this is perhaps the only argument which will induce the present graduates to consent to such sweeping reforms as those contemplated.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 29 to July 5, 1890.

KEEFER, FRANK R., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, will report in person for duty to the commanding officer at Fort Leavenworth, Kan. Par. 6, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

RAYMOND, THOMAS U., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, will report in person for duty to the commanding officer at Fort Sherman, Idaho. Par. 6, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

SNYDER, HENRY D., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, will report in person for duty to the commanding officer at Fort Reno, Indian Terr. Par. 6, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

SMITH, ALLEN M., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, will report in person for duty to the commanding officer at Fort Snelling, Minn. Par. 6, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

HEYL, ASHTON B., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, will report in person for duty to the commanding officer at Fort Niobrara, Neb. Par. 6, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

CLARKE, JOSEPH T., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, will report in person for duty to the commanding officer at Fort Riley, Kan. Par. 6, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

CORBUSIER, WILLIAM H., Captain and Assistant Surgeon. Relieved from duty at Fort Lewis, Col., and will report in person to the commanding officer at Fort Wayne, Mich., for duty. Par. 7, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

GARGLING: ITS PROPER METHOD AND SPHERE OF USEFULNESS.

By H. L. SWAIN, M.D.,

NEW HAVEN, CONN.,

LECTURER ON DISEASES OF EAR AND THROAT IN THE MEDICAL DEPARTMENT OF YALE UNIVERSITY.

WHEN it was that man discovered the art of gargling, or by what means he came to develop this peculiar process, neither history nor tradition gives us any clue. Suffice it to say, that from the remotest times man has known what "to gargle" meant, as is evidenced by the existence of words signifying the act, usually euphoniously, in so many of the ancient languages. Naturally, the acute observation of the first physicians did not overlook this method of applying remedies to disease, and so the first records of medical practice contain abundant references to gargles as being used in the treatment of the sick. Experience led these observers to believe the gargle to be of value, and they all refer to the act as something known by everyone, giving no direction as to the method of its performance. In this, however, they were not far behind their representative brethren many centuries later, as a glance through literature will convince anyone. Even to-day a large number of authors consider gargling as of so little importance, or rather as so thoroughly well understood by everyone, as to need no further comment than merely to mention the name.

The Greek and Roman physician distinguished between mouth-washes, collutions, and gargles, gagarismata, a difference to which we of to-day still adhere.

The practitioner of later centuries prescribed both forms of "washes" in great abundance, and our forefathers, in the days of influenza and of bleeding, did not forget nauseating mixtures with which they helped their patients to recovery. With the introduction and general use of the laryngoscope a more exact method of diagnosis led to a reaction against gargles, as being too diffuse in their effect upon parts within the throat, and they have been largely superseded by the spray, pencil, and insufflation, not forgetting the douche or syringe, until now many an author doubts whether gargles are really entitled to even a meagre consideration as of therapeutic value. But all authors are not agreed in this neglect of gargles, and believe there is yet a field of usefulness open to them. Let us for a moment contrast some of the modern ideas.

Take, for example, Morell Mackenzie,[1] in his exceedingly valuable treatise, who says: "The use of gargles is too well known to require any explanation, but the author has never found them to be of service in diseases situated behind the anterior pillars of the fauces. Their employment is especially indicated in chronic affections, the tension necessary for the execution of gargling being often injurious in cases of acute inflammation."

Prosser James[2] claims something more for the fluids in question and approaches, in his remarks upon the act of gargling, very nearly to the method which the writer will later advocate. He says that the act will vary largely with the individual. "Accordingly we find some persons never learn to gargle properly, while others achieve what at first seems impossible. The majority of patients, in point of fact, require some instruction respecting the end to be attained. In using the mouth-wash the velum and uvula descend so as to cut off all communication with the pharynx. In gargling, as frequently understood, the result may be almost the same, the liquid coming in contact with the anterior surface of the velum and uvula only. If, however, the patient should now raise the velum, as many can do, some of the liquid will flow into the pharynx. There it produces a desire to swallow, and unless the patient can control this, some of it will pass into the œsophagus and stomach. Some persons, however, instead of yielding to the desire to swallow, suddenly jerk the head forward, and a quick, forcible expiration taking place at the same moment, the liquid is expelled through the nose. What they do involuntarily can be accomplished by others deliberately and without inconvenience." Both this author and Lennox Browne[3] quote the method of Guinier for "laryngeal gargling." Browne is quite as much in favor of gargles as is James and quotes the von Troeltsch method at length.

Among the German writers opinions are advanced which are also very much at variance; the majority of those to whom I have had access, however, have chimed in more or less with von Troeltsch,[4] who is very unsparing in his recommendation of the "swallowing movements," especially in chronic catarrhal affections of the pharynx and naso-pharynx. In favor of gargling he says, speaking of the treatment of chronic aural catarrh: "Great influence is exerted upon the mucous membrane of the pharynx by frequent gargling, both when executed with simple cold water or weak salt solution, and when the complicated mixtures are used. Of these latter, such as contain alum or iodine are especially good for the purpose in view." Referring to the use of iodine as a gargle, he makes the observation: "Iodine as a gargarism has more than a simple local influence; I have frequently seen goitre grow much smaller, as also women who speak of a diminution in their bodily size or of a mild atrophy of the breasts. In a like manner, iodine gargarisms appear to have an influence toward resorption in the ear." And further, he says of opium, in a gargle, that it has often a decidedly soothing influence upon neighboring parts. After some extended remarks as to the rationale of the gargle as carried out by himself, he states: "Regular, energetic gargling, even with simple cold water or weak salt solution, is, therefore, of very marked value in cases of chronic pharyngitis, not only that thereby every retention of secretions is avoided and normal removal of the same evidently favored, but also that a certain amount of gymnastics of the pharyngeal muscles is sure to take place." He places most of the good effects of his method of gargling on the basis of a mechanical or gymnastic influence, supporting his propositions by the following statement of facts: "I can assure you that this is no mere theoretical speculation, but that I have surely seen good results, often with difficulty to be accounted for, come from simply gargling with cold water, when the latter has been done in the right way several times daily, using at each time at least one-half pint of fluid." Following in his footsteps many German writers, as Fränkel,[5] Vogel,[6] Wagner,[7]

Wendt,[8] Ewald,[9] von Ziemssen,[10] and Schwartz,[11] are favorable to gargling, giving it attention some more, some less; a few, as Strümpell,[12] Tobold,[13] and Rühle,[14] positively affirm that gargles are useless, except in cases of trouble anterior to the pharynx. But of all, Hagen[15] seems to be the most enthusiastic for the general use of gargles, and most successful in his method, which later will be given *in extenso*.

Of French authors the writer has not much to state, but only in Trousseau[16] did he find any marked favor toward gargles.[17] Here frequent mention was made of the use of gargles in throat affections, but of methods or the scope of the gargle not a word was found.

In turning our attention to American writings, we shall not find our authors any more at unity as regards the value placed upon gargarisms than has been our experience with foreign observers. Still there seems to be a greater tendency toward their use, and few are the authors who do not make some mention of them. Perhaps the spirit of many will be stated in no better way than to quote from Laurence Johnson.[18] "Some prominent laryngologists restrict the use of gargles entirely to affections of a chronic character and situated not farther back than the anterior pillars of the fauces, holding that the pain induced by their employment in acute affections more than counterbalances any benefit derived. It seems to me, however, that the restriction is quite too stringent. We must take patients as we find them and prescribe remedies, often because of their availability rather than that they are best. Comparatively few patients are so situated as to admit of all the care required to produce the best results of treatment. Of those suffering from the lighter forms of throat affections, whether acute or chronic, this remark is especially true, and in such cases gargles will continue to be prescribed and used, even though more exact and efficient methods might yield better results. And regarding their rejection in acute and painful affections of a graver character, such as tonsillitis, diphtheria, and the sore throat of scarlet fever, notwithstanding the dictum of high authority, I believe that a large body of the profession, confirmed in their opinion by the results of their experience and observation, will continue to employ them, and, I think, too, with satisfaction to themselves and benefit to their patients."

While many will be willing to coincide in the above remarks, others of equal probity either mention gargles not at all, or put them down as not getting deep enough into the throat to be of any value. Mention may be made in this connection of Flint,[19] Seiler.[20] Buck,[21] and Solis-Cohen,[22] as a few notable examples. Which are to be believed?

Becoming interested in studying these differences of opinion the writer searched back among the older authors for their records, and the result was, that much which was novel was found, which latter he begs to bring in brief to your notice.

Beginning with the oft-quoted sage, Hippocrates,[23] we find him recommending in quinsy, hot water as a gargle, and using it freely to lessen the inflammation and promote absorption. He does not limit himself, however, to simple water, giving the following as of value: A decoction of wild marjory, savory, parsley, mint, a little alkali (nitrum), and honey-water, to which a little vinegar is added. Of exact quantities, or of the method of preparation he does not speak, stating only that it should be used warm.

Aretæus,[24] also a Greek, refers to gargles in ulcerative angina, and makes a distinction between collutions and gargarisms. He recommends the use of astringents and demulcents for the healing of the ulcers in the throat.

Celsus,[25] who was a wonderfully acute observer and systematic writer, divides gargles into such as are soothing, astringent, and stimulating. He advises their use in quinsy, simple tonsillitis, ulcerations after quinsy, and diseases of the ear, quite astonishing us by particularly recommending gargarisms in cases of tinnitus aurium. As v. Troeltsch says, this is the more remarkable, "as it is by no means certain whether he knew anything about the Eustachian tube, which was surely noticed before his time." Celsus makes no attempt at explanation of the rationale of the working of gargles, but simply recommends them under "Curatio Sonitus Aurium," as a heading.

Dioscorides,[26] was quite favorably disposed toward gargarisms, and recommended them extensively in all affections of the mouth and throat, distinguishing between collutions and gargarizations. He speaks at length of a large number of waters and decoctions, which he classed under the two heads of demulcents and astringents.

But of all the more ancient writers, the great commentator, Galen,[27] is perhaps the most generous in his mention of gargles, giving them an extensive notice in the discussion of medicines best employed in diseases of the mouth and throat, to which class of remedies he gives the general name of "stomatica." These latter were electuaries, powders, or fluids, a distinction being made between mouth-washes and gargles. He gives a large number of compound prescriptions for the various mixtures, being himself strongly in favor of mulberry juice, unchanged in acute, mild inflammations, but to be increased in effectiveness by the addition of many and varied astringents or stimulants, mostly fruits or herbs, when the inflammation took a severer form. In this last use of gargles he voices the opinion of other authors whom he quotes at length, giving their favorite prescriptions. Heras, Andromoclias, Creto, Aristocles, Antipator, Harpocras, Asclepiades, Hippocrates, Archigenes, Heraclides, and Apollonius. From this array of names it will be very evident that at that time, and before, gargles were held in high repute and much used. Not a few of these names he quotes in connection with the use of warm gargles in angina.

In his observations on the nature and use of matters—animal, vegetable, and mineral—Pliny,[28] the naturalist, speaks of many substances and mixtures as being used as gargles, viz., decoctions of wild cabbage and supplejack (vitis pampinorum), and sheep's milk. For spitting of blood, to be used only as a gargle, care being taken that none of it be swallowed, he speaks of the following mixture: Salt, thyme, vinegar, and honey, proportions not stated. Another recipe is multipedes, pigeon excreta, with raisin wine.

Copying from the earlier Greek and Latin writers we find in the Sanscrit Ayurvéda of Susrutas[29] and in the Arabian of Avicenna[30] ample reference to gargles. The former speaks of sternutatoria or snuffs, eclegmata or

electuaries, and gargarisms, giving a number of pleasant prescriptions. As a gargarism sesame seeds, blue lily, mustard seed, sugar-cane, and milk with honey are the ingredients of an infusion intended for "a feverish mouth, to drive away the heat." Avicenna quotes very largely from Galen, and gives a number of "recipes" for throat disease. One which Galen, and others after him, recommended very highly was used as an electuary in throat troubles, but when the patients were affected with bronchitis then some of the electuary was dissolved in asses' milk and gargled. The electuary is very aromatic: Spikenard, cardamom, malabathrum (both the Indian and the mixed), sweet-flag, cinnamon (two varieties), myrrh, costus and liquorice-root, mandrake juice, and saffron; other details are omitted.

To judge from Camerarius,[31] who gives us what was known in medicine from the eighth to the twelfth centuries, considering each century by itself, one would conclude that but little was thought of gargles in that time. He refers at length to the use of vinegar in catarrh and bleeding, and discharge from the nose, the vapors of the heated liquid being referred to as markedly stimulating, but not a word about gargling or the use of collutions until, when speaking of the twelfth century, he remarks that those persons who cannot take any alcoholic stimulants on account of the disease with which they are afflicted, would receive great gratification by holding some wine in the mouth. Later writers refer to gargles as used at this time, and it is probable the author quoted did not deem them of enough importance to make mention of them.

In the sixteenth century we have a variety of works which give us the state of medicine in these and previous times. Some of the writers, as also in the next century, are very explicit about the descriptions of the disease and the various symptoms, but, like Hippocrates, they say little about the treatment. We therefore find Brunfels[32] and Cassius Iatros[33] not mentioning gargles, while in contrast Girolamo,[34] Fernellius,[35] and Mathiolus[36] speak often of them. Girolamo in "Morbus Gallici" gives a very much used gargarism made from a decoction of privet (ligustrum), plantain, and cytinus, a parasitic plant, into which alum, dregs of vinegar, soda, and armenian bole are placed. This was to be used when there were ulcerations. Mathiolus, who quotes largely from Dioscorides, and Fernellius, who is very explicit in what he has to say, were both inclined toward complicated formulæ. For example the latter gives: ℞. Roots of marsh mallow and beets, ℥ i.; whole barley, liquorice, and dried grapes, ℥ ss.; cook in one pound of honey-water. In this let pillitory and sowbread (cyclamium) of the powdered root, grs. xl., be placed. Express the liquid and use as a gargle. Montanus[37] makes the curious observation in connection with using gargles in cases of catarrh with bloody sputa that he abstains from them, as they are to be looked upon as causing "a descent of matters (discharge?), for they loosen a great quantity of it." He then speaks of electuaries to be used in order to have the catarrh discharge through the mouth, lest it descend upon the breast. He writes very extensively about catarrh, much more so than any of his contemporaries, and yet the writer failed to find any other reference to gargarisms.

The following century was prolific in writers who limited themselves to the consideration of diseases, and did not tell us much about their therapy. Many, as Bellini, Baglivus, Cardamo, Diemerbeck, Fuchsius, Helmont, Heurnus, Willis, Zacuto, speak of head and throat diseases, but persistently refuse to pay attention to the therapy.

Paracelsus[38] speaks of using gargles when collutions would be a better word, for he is recommending them in diseases of the mouth. Riolanus[39] devotes considerable attention to diseases of the mouth, soft palate, tongue, and tonsils, and discusses catarrh in general quite at length, recommending many gargarisms. Sennert,[40] Rivière,[41] Stalpart,[42] Bonetus,[43] Morton,[44] and Chesneau,[45] all refer to the use of gargles, mostly of the demulcent type, into which they put, to render them stimulating, mustard, piper, vinegar, and the minerals. Rivière speaks highly of mulberry juice. Some, as Chesneau and Stalpart, refer to gargles only in connection with the details of certain cases, but not in general. Sydenham,[46] in considering the treatment of quinsy, says: "The following gargarism should be used, but not after the common way, but that it should be kept in the mouth without agitation till it wax hot, and then that it should be spit out and that it should be repeated now and then.

"Take of plantain water, and red rose water, and the water of frogs' spawn, each four ounces; the whites of three eggs turned into water by beating; of white sugar-candy three drachms, make a gargarism."

The eighteenth century came and went, leaving matters as they previously had been in regard to the use of gargles, at least no record of any changes in opinion has come to the writer's notice. Much that is interesting is found in writings, but owing to the similarity with what has gone before the abstracts will be short. Fothergill[47] and Huxham,[48] in their treatises on malignant ulcerous sore throat, speak of using gargles very extensively, and the former makes a different gargle for the different stages of the disease, particularly emphasizing the use of serpentaria root in decoction as exceedingly valuable in the above disease. Boerhaave[49] treated quinsy with steam and warm gargles, the latter being frequently repeated, and when impossible were replaced by the injection of warm fluids with a syringe. In this latter particular he imitates some older authors. Monroe,[50] Magern,[51] Mead,[52] and Friend,[53] among others, give us to know that they were accustomed to employ gargarisms quite freely, Magern recommending them in asthma to remove mucus. Motherby[54] defines gargarism as a small quantity of fluid which may be taken into the mouth and moved briskly about and then spit out. When employed in disease they should be more frequently repeated than is done in common practice. R. James[55] writes as follows: "Gargarism is sometimes taken in a large sense for every collution of the mouth. More strictly it signifies a liquid medicine, appropriated to affections of the mouth, gums, fauces, and larynx, received into the mouth and there used by way of collution without deglutition." He then quotes at length from Celsus.

Rounding into the present century we will simply glance at the opinions of a few of the many writers in its earlier half. Good[56] was a believer in active medication, as is noticeable in his treatment of quinsy: "After letting blood the throat should soon afterward be gargled with port wine, made still more stimulating by spices or other aromatics, or with strong decoction of bark, rhatany, catechu, very sharply acidulated with mineral acids, the aromatic or pungent cayenne vinegar, or charged with an

addition of cayenne pepper in substance. Mineral and metallic astringents in general want poignancy. Mezereon root also advantageously forms a basis of a gargle." In acute laryngitis with œdema—empresma laryngitis—the same author would, in active, dangerous cases, gargle with ice-water, and put ice on externally to keep inflammation in check.

On the other hand, Doubb, Saissy, Green, and Thompson,[57] who write about the same period, give no notice to gargles. The latter gives accounts of epidemics of influenza from the year 1511 to 1837, and it is interesting to see how very few of the many authors quoted mention gargles at all, and only the earlier ones at any length. Wilde,[58] in writing on the ear at about the same time as Green and the foregoing, speaks of gargles being of value in ear troubles, and that the good derived is probably in large part due to the exercise given the muscles of the palate and Eustachian tube.

The closing quotation of this historical sketch is taken from Quain's "Dictionary:" "With some persons the gargles go little beyond the uvula and base of the tongue, but if the head be thrown back the fluid can be made to pass into the cavity of the pharynx, and may even reach the larynx and vocal cords. The tension of the muscles in thus throwing back the head is apt to provoke efforts at deglutition, so that sometimes small portions of the gargle may be swallowed; and occasionally the effort terminates abruptly in the patient's jerking his head forward and expelling the gargle forcibly through the nose."[59]

Having thus glanced down the records of the past, let us now review some of the various methods, for with all the differences of opinion and lack of detail methods are not altogether wanting. Troeltsch's method is, "Either sitting with the head bent back, or lying down, the person gargling lets an ample mouthful of fluid slip well down into the throat and then makes repeated strong movements of swallowing, without, however, allowing the fluid really to get into the œsophagus and be swallowed. . . . This act should be repeated until at least one-fourth of a litre of fluid has been gargled, and this amount must be used several times daily." In the edition of his work in possession of the writer he does not speak of the nose being held during the "swallowing movements," as others have quoted him. This addition to his method would assist in getting the fluids into the naso-pharynx.

Guinier, as quoted by James and Browne, gives a method of "laryngeal gargling." "A comparatively small amount of fluid only is taken into the mouth, which is to remain a little open, while the head is not to be thrown back, which latter would increase the desire to swallow. The patient should then protrude the lower jaw so as to draw away the epiglottis from the laryngeal vestibule, and on half-uttering a vowel sound the liquid drops into the larynx, and, provided the patient can prevent himself from taking an inspiration, those parts above the level of the vocal cords will be then thoroughly laved." As both James and Browne remark, and I have taken the above in part from both, the method is very hard to acquire, and few can ever expect to accomplish it.

Bosworth[60] says: "The proper method of gargling is to take the fluid into the mouth, throw the head back, and to commence the process of swallowing it; arresting the act, however, just at the point where the voluntary muscles act; that is, the patient should attempt to swallow the fluid, but should stop before the act is complete, and at a point where it is possible for him to expel it again. In going through with this procedure it will be found that the fluid can easily be allowed to pass completely into the pharynx, and down to the point where it will come in contact with the posterior wall, where it may be allowed to rest for an instant and can be ejected without its passing into the stomach."

Hagen's method,[61] which has never, to the writer's knowledge, been fully published, short mention of it occurring in a popular work,[18] is a modified or improved von Troeltsch method; in fact it grew out of the first publication which von Troeltsch made, in which he stated that a person must make a "half-swallowing movement" in beginning to gargle. He mentioned no farther direction as to the way in which this "half-movement" was to be carried out, and in thinking of a more definite plan Hagen states that he discovered his method. The later publications of von Troeltsch simulate very nearly the simple method which follows. The fluid which is to be gargled is taken into the mouth, so that the latter is a little more than half full. The patient is then told to bend the head back, open the mouth wide, and make a complete movement of swallowing, not allowing the mouth to close. The movement of swallowing must be as complete as if intending to send the fluid into the stomach, but if the mouth remains open none, or only a very limited portion, of it ever gets any further down than the œsophagus. The movement of swallowing completed, the air is allowed to "gurgle" through the fluid in the usual way as long as is possible; and when the fluid must be ejected, the patient, placing the tip of his tongue against the incisor teeth of the upper jaw, nods the head quickly forward, and the fluid runs out into the vessel waiting to catch it. If there is no obstruction in the nasal passages to prevent, and the patient has successfully followed instructions, the fluid on being ejected will pass up back of the soft palate and come out through the nose, moistening all parts of the naso-pharynx in its transit. Experience shows that while only one movement of swallowing with the mouth open is necessary, the presence of the fluid so far down the throat causes the desire to repeatedly swallow, but as long as the mouth remains open, far from being a detriment, it is a direct assistance to the perfect performance of the act. This fact is especially true of the last act of gargling, viz., the passage of the water through the nose. The repetition of the swallowing more perfectly dilates the pharynx, allowing the fluid free entrance to its cavity, and by so doing relaxes the soft palate, which is essential for the fluid to get from the pharynx out the nose.

At first glance this method differs but little from that of von Troeltsch, and in reality varies only in its greater completeness and the certainty with which it acts. The advantages are its extreme simplicity, allowing of easy accomplishment, the thorough cleansing of the throat and nose which is thus made possible, and the scope of its application. The difficulties in learning are easily surmounted. First, the act of swallowing with the mouth open is, to a person of normal amount of will-power and muscular control, a very easy matter. To some adults and to children it becomes difficult, and, as the tendency to close the mouth is very strong when one swallows, is only acquired in many cases by placing something between the teeth to prevent closure. Children of scarcely half-a-dozen years may be made to learn by giving them the fluid into the mouth, holding the head back, and, placing the thumb upon the lower incisor teeth, commanding the child to swallow. A small amount of pressure on the lower jaw suffices to keep the mouth open, and thus the gargling begins. By a little patience an adult may teach a child of even dull comprehension to gargle rightly. Adults, while learning, frequently profit by the placing of the crooked thumb between the incisor teeth while gargling, especially when they complain that the fluid all goes down the throat. This latter is frequently true of the first swallow taken each time when first beginning to gargle, and is probably due to the parts not being sufficiently moist; but occurring at other times, is usually due to a partial closure of the mouth, or to the back of the tongue rising up into contact with the soft palate. Many

[61] Moldenhauer, who at one time was assistant to Hagen, attempts an elucidation of the method in his book on Diseases of the Throat, but falls very far short of the mark as regards clearness or exactness.

patients complain of the inability to get the solution through the nose. A little practice suffices in most cases to make it possible to a greater or less extent, while some will get it the first time they try. If there is a hypertrophy or other obstruction in the lower part of the nose, but little or none of the fluid will be forced through, and this is perhaps the most frequent cause of lack of success in this part of the use of the gargarism. This the writer proved by, in many cases, removing the obstruction, and immediately the patient was enabled to get the fluid through the nose with comparative ease. While under the influence of cocaine, the turbinated swelling has retracted and for the time being gargling brought the fluid through in a copious stream, which was again impossible when the inferior turbinated tissue had assumed its former proportions, proving the relation of cause and effect beyond a doubt. Patients frequently speak of the gargle coming out one side better than the other, and this first side will naturally be found to be the larger of the two.

To some persons neither this nor any other method of gargling is at all applicable, owing to the disagreeable retching which it causes, and in a few no amount of practice is of any avail in overcoming this trouble. Occasionally this comes to pass in those to whom the gargle rightly carried out would be exceedingly valuable, *i.e.*, phthisical patients. In these latter the weakening effect of the retching and vomiting more than outweighs the good accomplished, and constitutes a very serious objection. But the number of those who are unable to master the art of gargling after faithful endeavor is very small indeed, so small as not to in the least stand in the way of the general use of this form of therapy.

As will have been already observed, many writers, both pro and con. have based their opinions of gargles upon very superficial evidence, apparently relying upon the statements of their patients as sufficiently accurate. That the fluids used as a gargle can be forced through the nose is a fact too often observed to be questioned, and it follows that in order to have traversed these latter parts, the fluids must reach the posterior pharyngeal wall and lower part of naso-pharynx, at least as high up as the lower lip of the Eustachian tubes. Further, if the fluid comes out the nose when the lower meatus is closed, then it must have attained an even higher level in the naso-pharynx than already mentioned, and can easily be believed to have gained access to the vault of the pharynx, laving all the naso-pharynx. This much we can gain by deduction. But how far down into the throat the gargle when rightly performed reaches, has never been very definitely proven, and the statements of patients are worthless. The laryngoscope helps us but little, and nothing is left but to gargle with colored liquids, observing the throat immediately afterward. The latter method was suggested by the already classical work of French and others, in proving that mucus from the nose reached the larynx. They introduced colored particles of insoluble powder into the nose, and later found them in the larynx or upon its edges. When the writer first began experimenting, many simple fluids were unsuccessfully tried, and it was only with ink that anything at all definite was obtained. At that time, some three years ago, the writer was not aware of St. John Roosa's [61] suggestion when he states : " Those who are sceptical as to the virtue of gargling and who claim that the process does not cause the fluid to wash the pharynx, will be convinced to the contrary by the following simple experiment. Let the posterior wall of the pharynx be painted with the tincture of iodine, and then a gargle of starch-water be used in the manner described (von Troeltsch's method), and the characteristic reaction will be found in the ejected fluid." Even this method did not give sufficiently accurate results, and finally it was proposed to follow this plan : First cleanse the parts by gargling with simple luke warm salt-water ; then a solution of ferric chloride, about ten drops of the tincture to a drachm of water and glycerine, was gargled in the right manner twice ; this was followed by a gargle of ferro-cyanide of potassium fifteen grains to the ounce. The result was that an intense blue color was given to all parts touched by the first iron solution. By this method, in himself and a medical student, Mr. E. A. R. Baldwin, the writer was able to demonstrate with absolute certainty that the iron solution had reached, first the outer or extra-laryngeal surface of the epiglottis, ligamentum ary-epiglottici, arytenoid cartilages, and posterior commissure. In the latter situation the color encroached further toward the interior of the larynx, and several times was seen on the upper and inner surfaces of the arytenoid cartilages and posterior commissure, working a short distance into the larynx ; but no coloring matter was seen on the false or true vocal cords, except very posteriorly, the first examination after gargling. The epiglottis got a slight edge of color on the posterior surface. The larynx was observed immediately after the expectoration of the fluid, and before any movements of swallowing had occurred except such as happened in the gargling. The pharynx was densely colored, and the naso pharynx as far as the Eustachian tube. When the attempt was not made to send the fluid through the nose, the posterior end of the inferior turbinated bone was reached, as also the posterior surface of the velum. The upper portion of the Eustachian tube was not reached. When the solutions were for the first time used Mr. B—— was an entire novice in the art, having never but once before gargled in the manner described, and this second time he was able, after several attempts, to get the water through the nose, notwithstanding that the task was rendered the more difficult by the presence of a considerable hypertrophy of the inferior turbinated body. When the color solutions were allowed to pass through the nose, the vault of the pharynx was colored a deep blue, as all other parts of the naso-pharynx and nose, the latter only inferior, however.

In the light of these observations we may safely state that the gargling by the above method does bring the fluid into contact with the mucous membrane from the larynx up to the tip of the nose, and therefore the reasonable belief that all of these parts may at one and the same time be influenced by whatever of medicament the gargarism may contain. Even the larynx itself cannot be allowed to escape from being included in the above statement ; for may we not conclude that fluids coming into so close relations with the interior of the larynx, as they have been proven to do, also affect these same structures ? The larynx is literally bathed by the fluids which fill all the large pyriform fossæ on either side, while above it is the liquid in rapid motion during the gargling.

The above conclusions being accepted, what a field of usefulness is open to a discreetly prescribed and rightly used gargarism ! And this is said notwithstanding all that is claimed for the more precise methods of application, for it is not to be supposed that the gargle will ever take their place, but only greatly supplement their action. Yet experience has proven that a simple gargle, long continued, perhaps for months and years, will accomplish as much and often more than the best of treatment with accurately applied local agents for a limited number of weeks. Since becoming acquainted with the method under discussion it has been the writer's custom to prescribe some simple gargle, as a weak salt solution (one-third to one-half a teaspoonful of common salt to the tumbler of water) in every case of throat or nose trouble of a catarrhal nature which came under his care, and such had been the practice of Professor Hagen for many years. The above was also true of all ear cases when it was at all a question of catarrh being a cause of the disease. The patients were also directed, as far as possible, to gargle their throats thoroughly just before coming to either office or clinic for treatment. While the above indiscriminate use of gargles may be open to the objection of being too general and inexact, yet it has been followed by the very best of results, care having always been taken to use no substance that might possibly do harm. There are a large

[62] Diseases of the Ear, p. 299. New York, 1874.

number of persons who, living in a climate such as exists in southern New England, and having had some trouble with the mucous membranes in nose or throat for many years, can never hope to be entirely free from trouble with these same parts, and it is in just such cases where the prolonged use of gargle seems in the highest degree beneficial. Such cases will come under notice from time to time and report, as well as present, objective evidence of great improvement from this simple treatment, faithfully pursued and, this in marked contrast to other methods of treatment which had previously been intermittently on trial. Its very simplicity is a strong recommendation.

The inquiry why these above-stated facts come to pass is not to be answered more completely than to refer the good accomplished to the regular and complete cleansing of the parts from the contained and retained mucus. This latter, as von Troeltsch remarks, is to the method in consideration all the easier accomplished in that the "swallowing movements" squeeze out the mucus from within the glands themselves, and this by virtue of the peculiar construction of the mucous membrane. The observation of a section of the pharyngeal mucous membrane, taken perpendicular to its epithelial surface, will, when under the microscope, develop how the glands are completely surrounded by the muscular fibrillæ whose contraction in the muscular movements of the throat must necessarily compress the mucus from the cavity of the gland toward the surface. Reaching this latter the vibrating fluid which is being gargled speedily removes it when it at least cannot be an irritation by having been retained too long. This explanation refers to the use of plain water or weak salt solution.

Buckmaster [63] relates a very interesting case of "submucous laryngitis" with œdema, in which he very successfully combated death by suffocation by the use of a stream of very hot water injected into the throat. Impressed by this case the writer has used, in all cases of acute laryngitis, tonsillitis, pharyngitis, and acute ear affections, very hot water, as hot as can be borne as a gargle. In the severest forms of quinsy this has been followed out, with but very few exceptions, where the mouth could not be opened at all. Used at the beginning of an attack of any of these acute affections, it has seemed often to help abort them, and if not succeeding in this, to very appreciably shorten the course of the disease and ameliorate its symptoms.[64] In several cases of œdema occurring in tuberculous laryngitis, when the increase in the size of the parts was sudden but not great enough to cause any symptoms of suffocation, very excellent effect has been obtained by gargling very hot water. In these cases the œdema was situated on the arytenoid cartilages, posterior commissure, and ligamentary epiglottici. Patients seem to find the gargle under all the above circumstances pleasant and agreeable, the relief to the pain being very considerable in cases of quinsy. This latter effect can be decidedly increased and prolonged by the use of a small quantity of some form of opium combined with the gargle. Of the use of ice-water as a gargle, very early in an attack of quinsy, the writer is not able to speak from experience, but it would seem objectionable unless one saw the cases earlier than they usually apply for advice.

In diphtheria, besides the inhalation of steam, hot gargles of lime-water, or some of the other "solvents of false membrane," so-called, are as successful in loosening the false membrane as the spray or swab. In cases of exquisite tenderness of the parts, the "swallowing with the mouth open" would scarcely be possible without great pain, yet, as regards the pharynx, considerable can be accomplished when a complete movement of swallowing is not made. If antiseptics are being used it would seem that in no way could the contact of the germicide and the false membrane or other parts of the throat be better achieved than by the gargle, that is, if aught of good is to be expected as a result of attempted antisepsis, then it will be by a gargle that this end will be most easily and surely attained. In the prophylaxis of diphtheria this is eminently true. After exposure to the contagion of this dread disease it would seem as though nothing could be more effective in removing any of the germs which might have lodged in the throat than a thoroughly executed gargle of some antiseptic solution. Moreover, this matter of the thoroughness in gargling may be one reason why younger children, who are unable to gargle well, are in a given set of cases oftener attacked, provided the same precautions have been taken in all. The recent article of Prudden,[65] who seems to have found a very constantly appearing streptococcus to be the cause of the disease, brings out the fact that, in a study of the habits of the germs present in the false membrane, corrosive sublimate is by far the most deadly foe they have among the list of antiseptics. A comparatively weak solution is deadly to the streptococcus when not encased in a false membrane; so, as a prophylactic, a solution of from one part to from five to ten thousand of water would be strong enough. The question would, however, naturally arise, Is there any danger in using such a solution as a gargle? In a person who is accustomed to its use but little of a gargarism ever gets into the stomach, even when the swallowing process is thoroughly carried out. But a novice necessarily would get more into the alimentary canal, as he would lose control of the parts, allowing much to be swallowed. Yet even this would not be sufficient in the weaker solutions to produce any constitutional symptoms, except in persons unusually sensitive to the effects of mercury. Another possibility is that the parts which are in contact with the solution are all of them capable of absorbing, and especially the buccal and pharyngeal mucous membranes. As regards the former the experiments of J. Karmel, as quoted by Vogel,[66] cover the matter very nicely. This observer made careful estimates of the amount of the medicament lost after holding in the mouth for from two to four minutes solutions of various substances. Of a solution of alcohol, five per cent., about twenty per cent. of the latter disappears; of a two per cent. solution of potassium chlorate, eight per cent. was lost, and of a solution of glucose, same strength as preceding, six and one-half per cent. did not return. These are by no means too small quantities to be set aside as not worthy of consideration. Also, it must be remembered that possibly the other mucous membranes may absorb faster than the buccal. But everything taken into consideration, a little calculation will show that, except in young children, there would seem to be nothing to fear from systemic influence, except in very rare instances of peculiar susceptibility. Next to corrosive sublimate in point of efficiency against the streptococcus of diphtheria, Prudden finds carbolic acid to present itself. In children it might be considered as somewhat the safer. And this gargling by those exposed to the contagion of diphtheria ought to be more general than is usual. Everyone so exposed should, at least once after such danger, gargle a half-pint of antiseptic solution in the most thorough manner possible, and those who are repeatedly exposed should do the same at least three times daily before eating. Some observers have even insisted that every child in the public schools should be made to gargle and submit to an examination of the throat at least once daily during times of danger. While not as radical as these just quoted, yet the writer must state it as his firm belief that many cases of diphtheria would not occur, were timely antiseptic gargling more urgently insisted upon by the physicians in attendance, and many a severe case be much the milder.

Of the other substances used as gargles, the writer's experience covers alum, iodine, potassium chlorate, the sulpho carbolates, and glycerine. This latter has been frequently used in cases of atrophic pharyngitis as an "after-gargle" to the usual salt solution. The results have been hard to either estimate or compare, but the testimony of patients shows subjective improvement in almost all the cases; but in only two cases has the writer seen any real improvement objectively result from this gargle where it was the only means adopted. Alum is seldom used by the writer, but potassium chlorate and the sulpho-carbolate of zinc have yielded very satisfactory results. In all cases weak solutions are used. The latter substance has occasionally supplemented the simple salt solution, the zinc solution being used intermittently, the other constantly. This method of treatment is especially valuable in treating the chronic pharyngitis of speakers, and the frequent naso-pharyngitis which so abounds in our midst. This is to be understood as taking place subsequent to such operative inference in the nose as may have seemed necessary or expedient. Of iodine there might be much said, but the quotation from von Troeltsch occurring earlier in the article does not seem too strong. When used as a gargle extra care must be taken of the teeth, and the strength varies very largely with the individual. The most convenient way to prescribe it is to dissolve it in glycerine with potassium iodide, and arrange it so that a teaspoonful to half a tumblerful is the right strength for the patient to use. It should not irritate the nose when it passes through it. While these remarks might be further illustrated by many histories taken from recorded cases, still enough has been said to support the writer in the following conclusions:

First. That gargles when rightly used reach the larynx, and at the same time can be brought into contact with all the accessible overlying parts of the upper air-passages.

Second. That the method herein advocated leads easily and surely to the above results.

Third. That the opinions of authors, having been so radically different as regards the value of gargles, have led to a general neglect of a most valuable adjuvant in the treatment of affections of the upper air-passages.

Œdema of the Glottis Caused by Iodide of Potassium.—Dr. A. Groenow, of Breslau, has recently reported several cases, from his own practice and elsewhere, of a peculiar form of iodism, manifested by acute œdema of the glottis. In all he refers to nine cases; two are from his own practice, the remainder are reported by Foerster, Fournier, Fenwick, and Malachowski. On reviewing these, the author draws the following conclusions: 1. That the œdema, which is sudden in its arising, takes place early in the administration of the drug, generally within twenty-four to forty-eight hours; and that its intensity may be such as to call for tracheotomy. 2. That the quantity requisite to call forth the symptoms varies from the lower limit of three grains upward; in one case, though there were slight throat symptoms earlier, yet it was not till the sixth day, when about two hundred grains had been taken in all, that severe dyspnœa set in. 3. That other symptoms of iodism may be quite absent. 4. That the cause of these exceptional effects is not the presence of impurities (iodates), but that the pure drug is alone sufficient. 5. That local laryngeal affections could not be shown to be present and to have predisposed the part to the œdematous outbreak. 6. That the phenomena must be explained by the word idiosyncrasy. 7. That in some cases the idiosyncrasy persists, but that in others it rapidly disappears, the patient becoming tolerant of the drug. The author lays stress on the fact that it is during the early part of an iodide course that this trouble is most likely to arise, and that watchfulness during this stage may avert a dangerous complication.—*British Medical Journal*, May 10, 1890.

A NEW METHOD OF OBTAINING SMALL QUANTITIES OF STOMACH CONTENTS FOR DIAGNOSTIC PURPOSES.[1]

By MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY, NEW YORK.

Mr. President and Gentlemen: The chief progress made in the branch of diseases of the stomach during the last two decennials lies especially in the field of the chemical condition of the stomach. Nothing is more rational than to examine the work accomplished by an organ in a diseased condition. It is now possible to determine, almost with certainty, by exact examination of the stomach contents, whether the stomach delivers its juices normally or not. The determination of free hydrochloric acid here plays a main rôle, for it forms one of the most important products of the stomach secretion. As is well known, the stomach contents are obtained by means of a tube and Ewald's "expression method."

Notwithstanding the great importance of the results obtained by a chemical analysis of the stomach contents—still this new method has as yet not generally been used by the medical profession. On the one hand an exact chemical analysis of the stomach contents absorbs too much time, and on the other the examination by means of the tube is often unpleasant and difficult both for the patient and even for the physician. Therefore any method which aims at rendering less difficult, even in a small degree, the examination of the stomach-contents, must be welcome to the practitioner, even should there be lost by this method some of the minor details; for it is certainly better to have something objective, than to be merely dependent upon the subjective complaints of the patient.

Having these points in view, Guenzburg[2] tried to avoid the introduction of the stomach tube. This author, in 1889, had his patient swallow potassium iodide enclosed in small rubber bags and fastened by fibrine threads. After the disappearance of the fibrine by digestion the rubber bag opens and the potassium iodide can now be absorbed. As soon as iodine is detected in the saliva, we are sure that the fibrine has been digested, and from this Guenzburg concludes the presence of hydrochloric acid. But this method, though ingenious, is not adapted for practical purposes. For, on the one hand, it causes the necessity of examining the saliva for quite a period of time (one to two hours); on the other, the appearance of iodine in the saliva does not conclusively prove that the fibrine has been digested in the stomach. The rubber bag may have escaped from the stomach into the intestines, the fibrine may have been digested there, and the potassium iodide absorbed. Thus we cannot make any decided conclusion as to the stomach-secretion by this (Guenzburg's) method.

Another simple method originated with Edinger.[3] This author already, in 1881, fastened a small sponge to a silk thread, which he caused his patient to swallow. After several minutes he took the sponge out of the stomach of his patient and examined the expressed contents of the sponge for hydrochloric acid. But Edinger's sponge-method lacks in the following two points: Firstly, the sponge is partly expressed during its withdrawal through the narrow points (cardia and introitus œsophagi), and thus loses much of the obtained stomach-contents; secondly, it absorbs fluid from the moisture of the œsophagus and pharynx. Thus the few remaining drops of stomach-contents in the sponge are obtained impure (*i.e.*, mixed with other fluids), and sometimes are changed in their chemical condition.

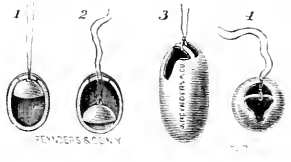
In order to avoid these drawbacks I devised this little instrument, which I shall have the pleasure of showing to you this evening.

[1] Read and demonstrated in the Section on Practice of the New York Academy of Medicine, May 20, 1890.

[2] Guenzburg, A.: Deutsche medicin. Wochenschr., 1889, No. 41.

[3] Edinger, L.: Deutsche Arch. f. klin. Med., Bd. 29, p. 555.

My original idea was to construct the apparatus in such a way that it would enter the stomach closed, there open, be filled with the contents, and would again close while withdrawing it. For this purpose I have simply put two hemispheres into each other in such a way that the external occluding hemisphere, though larger, had a smaller opening diameter than the occluded hemisphere. To the occluded hemisphere a thread is fastened. As long as the apparatus hangs on the thread the small hemisphere occludes the orifice of the larger one, and the apparatus remains closed (Fig. 1). As soon as the apparatus comes



into the stomach and swims in the fluid, the lid must by its gravity fall down, and in this way the apparatus opens, and any fluid of the stomach can flow into it (Fig. 2). When taking the apparatus out by pulling the thread, the lid closes the aperture immediately. Here are two apparatuses constructed upon this principle. But I regret to state that they did not prove practical, for the reason that the opening is too small and the fluid cannot enter into the apparatus freely enough. I therefore decided to omit the lid altogether.

The apparatus which proved to be perfectly adapted for obtaining small quantities of the stomach-contents, and which I have the pleasure of presenting to you now, consists of a small oval vessel ($1\frac{3}{4}$ ctm. long, $\frac{3}{4}$ ctm. wide) made of silver; on the top of the same there is a large opening with an arch over it; on this arch a silk thread is tied (Fig. 3).

Method.—In order to obtain a sample of the stomach-contents, one proceeds in the following way. The patient is asked to open his mouth widely and the little vessel is placed on the root of the tongue (almost in the pharynx); the patient is now to swallow *once*. The vessel comes after a short time (one-half to one and one-half minute) into the stomach. This point can be easily found by the length of the thread from the vessel to the mouth; it equals the distance from the teeth to the cardia, which is usually 40 ctm. It is advisable to make a knot on the thread marking 40 ctm.; when this knot comes into the mouth, then we are sure that the vessel is in the stomach. The vessel is then left for about five minutes in the stomach and thereupon withdrawn. During withdrawal of the apparatus a resistance is usually felt at the introitus œsophagi. To overcome this difficulty, when the apparatus is at that narrow point the patient should either deeply expire or swallow *once*. By the act of swallowing the larynx is pushed forward and upward, and thus the passage is free.

If the stomach is not empty, the vessel returns filled, and the amount is sufficient for making qualitative tests for free hydrochloric acid and the rennet ferment. This little apparatus may be called a "stomach-bucket."

In people suffering from an abundant secretion of the mucous membranes it might happen that the little vessel becomes filled with mucus before entering the stomach. [In emptying the vessel, it is always easy to distinguish real stomach-contents (namely chyme) from plain mucus.] In case we find principally mucus in the vessel, it is necessary to make the trial again and to cover the opening with a thin gelatinous capsule, which keeps the mucus away from the vessel on its passage to the stomach; there the capsule is dissolved, and the stomach-contents can now enter into the apparatus.[1] On its return from the stomach, the "bucket" being filled, the mucus cannot to any extent enter into it.

This way of making a qualitative stomach test is, on one hand, for the physician as well as for the patient, more simple and handy than that with the tube; on the other, it does not cause any exertion to the patient, and even in ulcer of the stomach there is no danger whatever from a hemorrhage in consequence of the examination. For this reason this method seems to be especially recommended in all cases where there is suspicion of an ulcer of the stomach, and where one likes to avoid the tube. It is also appropriate to the general practitioner, who does not intend to make an exact analysis of the stomach-contents, but who merely disires to determine whether there exist free hydrochloric acid or not.[1] For a full exact analysis of the stomach-contents naturally the tube cannot be avoided.

The best time for obtaining a sample of the stomach-contents is, just as usual, one hour after Ewald's trial-breakfast, or three to four hours after a trial-dinner.

If the sample from the "stomach-bucket" give a positive reaction of hydrochloric acid (with Congo or Guenzburg's phloroglucin-vanillin test) then the same is made use of at once; but should it prove negative as to the presence of hydrochloric acid the obtained sample must be examined more minutely, and if it is found to be mixed with much mucus then it is necessary to obtain another sample with capsule-covering, as described above.

This method of obtaining small samples of stomach-contents gives, besides this, the opportunity to examine several other points having reference to the œsophagus and the stomach, as for instance: 1, The permeability of the œsophagus; 2, in extracting the apparatus, the determination whether the cardia is closed (in this case a certain resistance is felt, as soon as the vessel comes to the cardia), and then what distance there is from the cardia to the teeth; 3, one is enabled, as soon as the "bucket" is in the stomach, to study partly the contractions of this organ, by observing how far, with what force, and at what intervals the thread is pulled farther in, for the thread *alone* affords too few supporting points to be moved by the contractions of the œsophagus. In this way every traction of the thread hints at a farther locomotion of the apparatus in the stomach.

These last points, however, I have studied too little as yet to be able to present you the value of such observations, but I hope, after numerous investigations, I may be able to do so. I would then feel honored, Mr. President and gentlemen, to impart to you the facts resulting from my experiments. This evening I would yet desire to demonstrate upon several patients the method described for obtaining stomach-contents.

[This lecture was then followed by the demonstration.]

122 East Fifty-ninth Street.

[1] It happens but very seldom that the opening of the "bucket" becomes obstructed with some mucus of the stomach in such a way that no contents can enter into it; then the trial must be repeated.

THE AUSCULTATORY PERCUSSOR.[2]

By L. L. SEAMAN, M.D., LL.B.,

late chief of staff, blackwell's island hospitals, new york.

In the furtherance of a profession which has long since broken away from the traditional empiricism of the past, in its observance and devotion to both science and philosophy, the development of any new mechanical appliance for the perfection of diagnostic investigation requires neither apology nor justification. It is enough that there is a work or service yet inviting professional research, and a sufficient provision for it, in the world of discovery and invention. Indeed, this absolute *entente cordiale* between the physician's art and science, both speculative and practical, is a matter of supreme moment, as well as supreme satisfaction. Correct and exact knowledge of morbid conditions is indispensable to the practice of our profession and in no department of

[1] The Stomach-bucket is manufactured by Messrs. J. Reynders & Co., 303 Fourth Avenue, New York.

[2] Read before the New York Academy of Medicine, May 15, 1890.

physical diagnosis has the practitioner encountered more critical and perplexing difficulties than in the exercise of percussion and auscultation.

The auscultatory percussor is an apparatus constructed on strictly scientific principles, by which the practitioner is enabled to realize and delicately discriminate the percussion note, while adding to ordinary percussion the value of mediate auscultation, thus securing a trustworthy and explicit tonal reading of internal conditions. In conjunction with the Edison phonograph it also furnishes an instrument whereby percussion notes may be accurately registered.

I submit the instrument and its mechanical appliances, together with an analysis of the acoustical laws under which its researches are utilized. In further elucidation

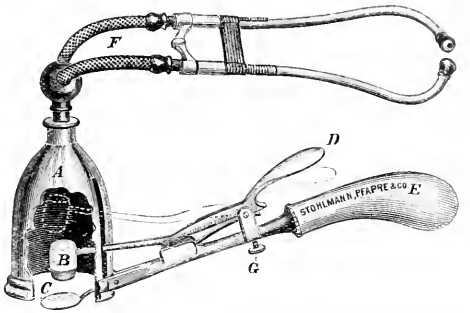


FIG. 1.—In the accompanying illustration A represents the bell-shaped receiver or object end; B, the percussion hammer; C, the pleximeter; D, the hammer-handle; G, the set-screw by which the intensity of the percussion note is regulated; and F, the auditory tubes.

of the scientific data represented in this invention it may be observed that all forms of matter capable of resonant vibration respond in characteristic and fundamental notes. For, says the "Encyclopedia of the Art of Acoustics," "the shortest and most sudden noise has its peculiar character." But it must be borne in mind that these vibrations in passing from one medium into another become modified, if not changed in character, after the analogy of transmitted light, or radiant heat; and any variation in the media through which they pass causes a correlative variation in the character of the vibration itself. On this single fundamental fact or principle of tonal or resonance development the science of diagnostic percussion depends. In the percussion of a healthy thorax a sound is developed which in degree and quality of sonorousness is accepted as a normal standard. This standard, however, is not uniform in different individuals, but varies according to the varying thickness and elasticity of the chest-walls, and to other attendant physiological conditions, the normal standard for any individual being determined by comparative percussion of both lungs, or of one area of a lung with the corresponding area of the other. It is obvious that pathological conditions occasioning derangement or disturbance of legitimate functions give rise to changes or modifications in the note of percussion which the practitioner often interprets with great difficulty. Deviations of resonance in the incipient stages of disease are exceedingly subtle and are identified with extreme difficulty at the very stage when their full significance is of paramount importance. This instrument has been devised especially to secure a more truthful reading of these obscure variations in resonance, and thus to facilitate the examiner in arriving at a more exact diagnosis.

It will not be disputed after reflection that all sonorous vibrations falling within the range of our perceptions have their exterior correlatives as normal conditions of the surrounding atmosphere. To illustrate, if the air could become actually visible as it generates and continues the sound in response to a stroke of the percussor, we could clearly distinguish and identify those conditions of motion on which the sound depends; while its quality, for the moment, would be determined as a condition or state of the volume of atmosphere under examination.

Tyndall graphically compares the striking of a cannon-ball on a target to an atmospheric particle striking the tympanitic membrane of the ear. "The sonorous effect is expressed by the same law as the mechanical effect." "All, in fact," he remarks, "that goes on outside ourselves, is reducible to pure mechanics; and if we hear one sound louder than another it is because our ears are hit harder in one case than in the other.

Therefore, in striking a blow we set in motion a volume of matter which augments as the square of the distance from the starting-point, while the intensity or loudness of the sound thus produced diminishes in the same ratio, or inversely as the square of the distance. Thus it becomes evident that if a mechanical impulse be communicated to any particle of air, and thence to the surrounding atmosphere, and permitted to radiate without interference, it must reach each more remote point with an energy which is constantly diminishing under a uniform ratio; for the reason that the original energy of impulse is communicated to a constantly increasing volume of atmosphere at rest.

The propagation of sound is governed by the same laws of reflection observable in the transmission of light: the angle of incidence and of reflection being found equal under both acoustical and optical analysis. Divergent waves of resonance, therefore, may be duly gathered, concentrated, and propagated through the intermediary of properly adjusted reflecting walls, and delivered, unimpaired, with tonal truthfulness, at a desired aural focus in obedience to well known, clearly demonstrable laws, as may be seen by an examination of the following diagram.

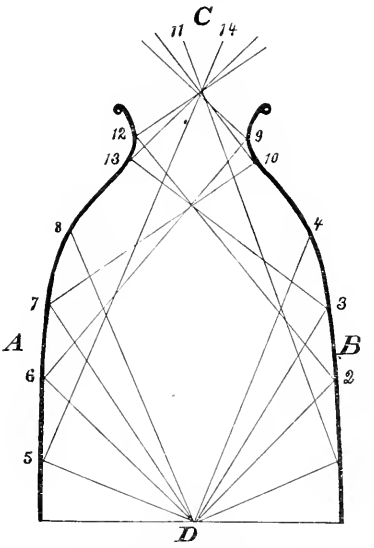

FIG. 2.—Let A, B, C, D represent the receiver or object end of the instrument; D, the point where the blow is struck; C, the entrance of the conducting tube. The lines D 1, D 2, D 3, D 4, D 5, D 6, D 7, D 8, represent sound-waves as they strike against the walls of the receiver; and the angles D 1, 11, D 2, 12, D 3, 13, indicate their reflection to the conducting tube, through which they are transmitted to the ears in all their intensity, after the manner of a speaking-tube or a whispering gallery.

The manipulation of the instrument invites close attention. The object end is placed directly over the area under examination. The thumb raises the lever, and when at a given height it is released, the action of the spring throws the hammer vigorously down, delivering a blow upon the pleximeter. The impulse thus imparted forces the air into sonorous undulations which, after de-

flection along the walls of the receiving chamber, are propagated without dispersion directly to the ears of the listener, be it observed, in isochronous delivery to both ears, thus securing the most perfect tonal report conceivable to scientific speculation.

The receiver does more than merely reflect and transmit the sonorous undulations. Since it is in immediate contact with the vibrating chest-walls, it takes on reciprocal resonance, which it communicates to the observer, thus intensifying the report. Thus the vibrations, instead of being suffered to radiate in every direction, are collected and delivered convergently to the auditory nerves; the lesser deviations, whether of pitch, duration, or quality, are sufficiently augmented to render variations from the normal standard immediately apparent.

Another distinct value of the instrument is that the force of the blow delivered may be graduated and regulated to the finest degree of nicety by a proper adjustment of the set-screw, varying areas may be examined and comparative results deduced with almost absolute precision.

Again, the stroke of the hammer is always exactly perpendicular to the pleximeter. Walsh, in his chapter on "Physical Diagnosis," in speaking on this point says, "the least variation in this respect will assuredly be attended with a difference in the sound elicited." It is apparent that the quality of the resonance must vary with the direction, as well as intensity, of the stroke. The least departure, then, of the percussory blow from the fixed perpendicular vitiates the accuracy of the examination. Nothing is clearer than the fact that the ordinary digital stroke is subject to perpetual variation, even under the exercise of the most intelligent precaution.

The shaft on which the percussor is fastened is so adjusted that the spring, while expending its force, throws the hammer a little beyond the line of centre, so that the blow is struck lightly and quickly, and the hammer rebounds very much as it strikes and rebounds from the string of a piano when a note is struck on the keyboard. By this means the pressure is removed the instant after the blow is delivered, so that the vibrations of the area under examination are neither interrupted nor impeded. The pressure of the pleximeter on the chest is also constant, and this, too, is an important consideration; for, says Walsh in the article just referred to, "no extrinsic condition modifies sound so much as the amount of force with which the pleximeter is applied."

By an additional object end, the instrument may be converted into a flexible stethoscope, identical with Dr. Cammann's. This instrument, according to Dr. Flint, so intensifies sound that auscultation is rendered available even to practitioners with impaired hearing. By the intermediary of the auscultatory percussor diagnostic percussion is also made practicable for this unfortunate class of the medical profession.

While explaining the practical operation and use of the instrument, stress was laid upon the fact that the report of resonance is delivered simultaneously to both ears of the examiner.

In further elucidation of this point, we refer to another law of acoustics, in obedience to which auditory sensations from a given sound are fuller and more perfectly expressed when delivered to both ears. This law is illustrated analogically in the use of the binocular field glass, and binocular microscope. This instrument is, then, a binaural auscultatory percussor in the isochronous conveyance of its tonal report to both ears of the listener—thus serving, while complementing the binauricular constitution of man himself, in his dual function of hearing as well as seeing.

When it is desired to register the percussion note, the binaural tubes of the instrument are replaced by a single one which is connected with the receiving funnel of the phonograph. The percussion blow is struck as before, and the undulations of sound are communicated directly to the diaphragm of the phonograph. This delicate mechanism registers the notes upon its wax cylinder, as illustrated on the specimens herewith submitted. These cylinders may be stored for an indefinite period, and the sound reproduced at will on the phonograph, with sufficient force to demonstrate the original notes.[1] With the assistance of the microphone these notes may be distinctly heard by a large audience.

When it is remembered that the "most delicate shades and variations of the human voice—music, whether instrumental or vocal, solo or multiple, in all its rhythm, melody, and intonation, the lowest as well as the highest notes, may be treasured up and reproduced, duplicated and multiplied indefinitely," it may readily be seen how the phonograph, aided by the auscultatory percussor, may be destined to play an important rôle in the medical teachings of the future.

There are objections to be anticipated and apprehended, as under all similar introductions of scientific and mechanical appliances in the furtherance of our profession. It may be urged that the investigator is liable to suffer confusion and disturbance of auditory impressions, since the instrument intensifies and augments resonances, which might prove misleading. Undoubtedly such objections would be formidable if the explorations were confined to but a single area of the chest; but they lose their force when it is remembered that the investigator will differentiate his conclusions from a delicate comparison over several chest areas; so that local dulnesses can be sharply marked out and intelligently interpreted. It is obvious that the profitable employment of such an intermediary, or of any untried mechanical or scientific invention, implies manual and technical dexterity and well practised intelligent manipulation, and especially a careful training of the hearing in the study and interpretation of resonances, before practical results may be secured.

Many of the objections so forcibly urged against the Cammann stethoscope may without doubt be ventured against the auscultatory percussor; such as "noises in the ears" produced by the pressure and presence of the knobs, resonance of the receiver, etc., but as Dr. Allison has already so admirably answered them they may be dismissed without further notice. Yet some good purpose may be served if I quote his words: "It is common to hear persons speak with disparagement against this instrument (the Cammann stethoscope) on account of the little evils above pointed out. But it would be better for such individuals to master a valuable aid than to carelessly and heedlessly throw it aside and prevent others from using it. All instruments require education and care; even the wooden stethoscope in the hands of a clumsy explorer may fill his mind with prodigious errors. In a difficult, in an obscure pursuit, in dealing with the lives of those confiding themselves to our care, we are imperatively called upon to think seriously, and to try, time after time, before we fling away any contrivance promising assistance in ever so slight a degree. To use skilfully a delicate instrument requires time and application, and this is no more objection than to the acquisition of a language."

Monthly Rhythm in Males.—Dr. Harry Campbell, of London, writes in *The Lancet*, asking for assistance from physicians generally to enable him to solve the question of menstrual periods in man. He believes that such a condition does exist, and suggests the following as a provisional hypothesis: Both sexes of the human species pass through a monthly rhythm, which begins in the embryo, and continues till death. That a monthly rhythm occurs in woman independently of so-called menstruation is manifest, for such a rhythm is easily detected during pregnancy and lactation, and after the climacteric; and he thinks it not improbable that a similar rhythm occurs in the male sex, and in girls before puberty.

[1] At the conclusion of the paper the notes of the cylinder were reproduced on the phonograph.

MEDICO-LEGAL CASES.

By HENRY A. RILEY, ESQ.,
NEW YORK.

CAN a person who murders another receive his whole property as legatee under the will? The New York Court of Appeals has just decided that he cannot. The circumstances of the case were remarkable, and were stated by the judges to be probably without a parallel in legal history.

In 1880 Francis B. Palmer made a will in which small legacies were given to his two daughters, while the balance of the estate was to go to his grandson Elmer E. Palmer, the only restriction being that his wife should have her support from the estate.

The grandson, Elmer E. Palmer, knew the provisions of the will, and in 1882, in order to prevent any possible revocation which might be unfavorable to him, poisoned his grandfather. The boy was sixteen years old, and was put on trial for the crime and convicted of murder in the second degree. He was sentenced to the State Reformatory and was serving out his term, when the action was brought to determine whether he could hold the property. The statute was clear on the point that a properly executed will could only be revoked by the intelligent act of the testator, and the will was conceded to be a valid one in all respects, and was unrevoked by the testator at the time he died. It is true that the Legislature never contemplated so unnatural a crime as that perpetrated by the boy for so sordid a motive, or it would no doubt have placed an exception in the statute to cover the case; but not having done so, could the plain provisions of the law be set aside? This was the problem before the court, but fortunately the abject reverence felt in former times for precedents and statutes did not have sufficient weight to overcome the common sense view of justice.

The reasoning of the court was convincing, and we quote as follows: "There was no certainty that this murderer would survive the testator, or that the testator would not change his will, and there was no certainty that he would get this property if nature was allowed to take its course. He therefore murdered the testator expressly to vest himself with an estate. Under such circumstances, what law, human or divine, will allow him to take the estate and enjoy the fruits of his crime?

"The will spoke and became operative at the death of the testator. He caused that death, and thus by his crime made it speak and have operation. Shall it speak and operate in his favor? If he had met the testator and taken his property by force, he would have had no title to it. Shall he acquire title by murdering him? If he had gone to the testator's house and by force compelled him, or by fraud or undue influence had induced him, to will him his property, the law would not allow him to hold it. But can he give effect and operation to a will by murder, and yet take the property?

"To answer these questions in the affirmative, it seems to me, would be a reproach to the jurisprudence of our State and an offence against public policy." The judge further said that the Civil Law and the Code Napoleon expressly provided that one could not inherit property from a person whom he had murdered, but that no country or state where the common law prevailed had thought it necessary to enact a law on the subject.

This failure to provide legislation required the court to fall back on the natural principles of justice and practically to make a law itself. This function of the courts is rarely exercised and would be open to great abuse, except in the hands of the most upright and scrupulous judges. So great was the disinclination to countenance court-made law, that two of the seven judges of the Court of Appeals felt obliged to dissent from the opinion of the others, although they recognized the enormity of the crime perpetrated by young Palmer. They said that it was important that laws should be obeyed, even though apparent injustice was occasionally the result.

When a life insurance policy is made payable to a different person than the insured man himself, it frequently happens that nothing can be recovered, because the payee has no proper interest in the life of the insured. The complications which grow out of this principle cause a very large part of the litigation over insurance policies. It is held almost universally that the interest which the payee must have is a pecuniary one; that is, he must owe the insured a support, or be under some obligations to him which might cause loss at his death. It is not necessary that the pecuniary interest be large or capable of exact computation, but there must be something more than affection.

A recent case goes over the ground thoroughly and reviews the decisions in the various States, showing that there is substantial accord between them all.

In general it may be said that there must be "a reasonable ground, founded upon the relations of the parties to each other, either pecuniary or of blood and affinity, to expect some benefit or advantage from the continuance of the life of the assured," otherwise the policy cannot be enforced against the insurance company.

An unusual case of extorting a confession was brought to light in a Florida court recently, and the alleged criminal was held not to be bound by the statements made under duress. The facts were as follows: The defendant was in the custody of a guard, charged with the murder of a man named Hammond. A rope was placed around his neck by the guard, who took him to where an inquest was being held over the remains supposed to be Hammond's, carried to the woods not far off, the end of the rope thrown over a limb, and the defendant was then told that his last hour had come; that he had to tell all about the crime with which he was charged. The accused denied all knowledge of the crime. The guard then tightened on the rope, let the accused down, and he again denied all knowledge of the crime. The rope was again tightened, and the prisoner then said if they would give him two minutes he would tell all he knew, and he then confessed that he was guilty, and the guard forced him to promise that he would "stick" to what he then said, and that he would stick to it in court. The guard then carried the prisoner before the inquest, where there was great excitement and talk of lynching, and he again confessed. The next day he was carried before a justice of the peace for preliminary examination, and there, in the presence of two of the guards whom he had promised to stick to what he first said, without counsel, without any caution by the justice, without being informed as to his rights, he again confessed. The court held that the last confession, although made under different circumstances from the others, was made under the same influences, and could not be used against the prisoner.

A CASE OF CONSERVATIVE SURGERY ON THE HAND.[1]

By LEONARD S. RAU, M.D.,
NEW YORK.

As far as I have been able to ascertain, the operation which I performed upon the case about to be described is a unique one, as I have been unable to find any similar case described in surgical literature. My excuse for reporting the case at so late a date is due to my constant efforts and hopes to find the patient. Unfortunately I am unable to do so, which fact I regret exceedingly, for it would be extremely interesting to see the man's condition four years after the operation. People who saw the man some months since assured me that he has perfect use of his hand and that it gives him no inconvenience whatever. The history of the case and operation is briefly as follows:

Franklin A——, aged thirty-seven, was admitted to

[1] Presented before the New York County Medical Association, May 19, 1890.

the Ninety-ninth Street Hospital on July 10. 1886. While working in a saw-mill his right hand was caught by the machinery, cutting off his thumb at the metacarpophalangeal articulation, and producing a compound, comminuted fracture of the metacarpal bone of the index-finger, which fracture began about one inch below the phalangeal articulation and extended up to the carpal articulation. There also existed a lacerated wound of the hand on the dorsal and palmar surfaces, extending as far as the metacarpal bone of the middle finger.

The patient was anæsthetized. the hand made thoroughly aseptic, an Esmarch bandage placed above the wrist. and then all of the fragments of the bone of the index-finger were removed. It then became evident that his index-finger would be useless without a metacarpal bone, but it did not seem right to remove it, as above the fracture the finger was entirely uninjured. It then occurred to me that by cutting off the head of the metacarpal bone of the thumb, and then bringing it over and wiring it to that portion of the metacarpal bone of the index-finger that remained, that this could take the place of the fractured bone and the man would then not have to lose his index-finger. This was accordingly done. Two holes were drilled into the bones, silver wire passed through them, and they were then approximated and brought in close contact. All of the superfluous and badly lacerated tissues were cut away, a drainage-tube was inserted, and the wound sewed up with a continuous catgut suture. The hand was then placed upon a splint and antiseptic dressings applied.

The patient progressed far better than I had anticipated, and on August 20th there was firm union between the bones. In the beginning of September the silver wire, which protruded through a small opening in the skin, was carefully removed. There was considerable anchylosis of all the fingers and some œdema. This, however, soon disappeared, and by the end of September, when I saw the man for the last time, he had excellent use of all of his fingers, and had a very useful and shapely hand.

Hoffmann Arms, 640 Madison Avenue.

Clinical Department.

TWIN PREGNANCY—ABNORMAL MENSTRUATION — PLACENTA PRÆVIA — BLIGHTED FŒTUS—ARTIFICIAL DELIVERY—RECOVERY.

By THEODORE POTTER, A.M., M.D.,

Indianapolis, Ind.

I was consulted August 3, 1889, by Mr. T——, in regard to his wife. He stated that she had for the second time passed her menstrual period, was suffering some pelvic pain, and had an almost constant feeling as though she would menstruate, yet the flow did not appear. Mrs. T—— afterward described it to me as a peculiar "stuffy" sensation which led her to think almost hourly that "something would break loose." I prescribed for her in a simple way, suspecting pregnancy, and gave directions as to her conduct. A week later she was somewhat relieved, but was having a slight discharge tinged now and then with blood. August 20th she slipped and fell in the doorway, but did not seem to experience any ill effects from the mishap. On the 27th she had a violent hemorrhage, losing, she said, nearly a quart of blood. On the 30th another smaller, but yet profuse, hemorrhage, both coming suddenly and almost without warning. On the 31st I was called to see the patient for the first time.

Examination revealed a slight oozing, the cervix being barely within reach. The uterus was about the size of one in the fifth month of pregnancy, irregular shaped and unusually hard. I suspected a fibroid tumor, no fœtal heart-sound detected, but the placental bruit was exceptionally distinct and located low down, as low as the stethoscope could be forced into the pelvis. Diagnosis: pregnancy, placenta prævia, perhaps complicated by a fibroid.

The cervical canal would admit the finger to but not through the internal os. Tampon applied. Another moderate hemorrhage followed removal of the tampon the next day.

September 3d the husband brought me, as ordered, the material discharged, which evidently contained placental tissue. I advised immediate dilatation and delivery, as the woman was already almost exsanguine. Dr. E. S. Elder saw her in consultation at midnight. Dilated the cervix with fingers and at once struck the presenting placenta completely covering the internal os. The life of the child being out of question, the finger was swept around, tearing loose and removing all within reach. Hemorrhage now ceased and the finger passed freely around an apparently empty cavity, in size about that one would expect to find at three months. Not finding the fœtus we supposed it had escaped with some of the clots. The uterus was still large, irregular and hard as described; but, after careful examination, and entertaining the suspicion stated above, we thought our work for the time ended. The deception was complete. for deception it was, as the sequel showed. The uterus was washed out with a one to five thousand bichloride solution, and as a precaution, a tampon applied.

Early the next morning I was called in haste, and found the patient bleeding and in a serious condition. Hastily cleaning my hand, I introduced it into the vagina, rapidly and forcibly dilated the now more open cervix to admit all my fingers, and removed the following: First, the remainder of the placenta prævia from the wall above the internal os, attached to it being the sac described below; second, a fœtus fully five months old; third, the placenta belonging and corresponding to the latter in size and appearance. I washed out the now really empty uterus with boiled hot water, and thus brought my patient's troubles to an end. Recovery uninterrupted and complete. She menstruated normally October 15th.

The portion of the placenta prævia removed at the second operation measured two by three inches, being apparently about two-thirds its original size. It was thin, dense, leathery, evidently blighted. Closely attached to it was a sac measuring one and one-half by three inches, containing a clear, straw-colored fluid, floating in which was a flattened, mummified fœtus. The latter, the limbs in the ordinary fœtal position, measured one inch. The ears, fingers, toes, etc., were well formed, and no doubt it was of the same age as the other. The sac containing it was closely adherent to its placenta over a circular area one and one-half inch in diameter around the attachment of the cord. The cord was one and one-half inch long and about the diameter of a large pin. There was nothing unusual about the larger fœtus; the uterine face of its placenta presented the unmistakable signs of recent bleeding.

The condition of things would seem to have been as follows: A twin pregnancy occurred; the lower placenta was prævia, not centrally implanted, but sufficiently near it to cover the internal os; the upper part of this placenta and its fœtus were pressed upon by the other product of conception. Perhaps this was the cause of the blighting and of the peculiar attachment of the sac. The fœtus died and mummified, while its placenta continued to grow, though imperfectly.

The reason of our being deceived at the first operation was that the small sac, being caught above, and the remainder of its placenta, after tearing away the part around the os, being thin and plastered tight against the uterine wall, there was presented to the finger the sensation of an empty, clean cavity. The uterus was contracting, the upper sac was made tense, and the breech of its contained fœtus presenting, a moment's thought will reveal how this added to the deception as to the shape and character of the cavity around which the finger swept.

The patient is an intelligent woman, aged thirty four. She has had five children, no miscarriages. The last three children are living and healthy; the first two were delivered with forceps after ergot had been given freely by a physician for some hours; both were dead, but with no evidence of disease. The youngest child is twenty-eight months old. She insists that she had missed but two menstruations, the hemorrhages occurring at the time the third was due. At least she had a uterine flow, proper in time and character, and nothing sufficiently abnormal about it to attract attention. She thought she was menstruating at those times, and hence when I saw her supposed herself about two and a half months pregnant, but could not account for the size of the uterus.

A number of interesting questions are suggested in studying this case. Was there a genuine menstruation as the patient thought? The explanation and possible diagnostic value of the peculiar sensation complained of when I was first consulted. What aroused the hemorrhages; was it the mere presence of the placenta prævia, the conditions arising with the fact that it was time for the menstruation to occur, or the fall of the week previous? Which placenta bled first; was it bleeding from the placenta prævia which excited the uterus, made it contract, and partially detach the other, or did the fall cause hemorrhage from the upper placenta, and thus start the final disaster? Both had certainly bled; they were carefully examined by the late Professor T. B. Harvey, who was positive in this opinion. Why did the blighting of the lower fœtus and placenta occur? was it due to their being caught and squeezed by the other, or was it the result of disease? Of the latter there was and is no evidence. Finally, I call attention without comment to the location of the supposed placental sound as a diagnostic factor. Small value is placed upon this sign by most authorities.

This case seems an interesting one and worthy of record, because of the peculiar combination of conditions which rendered it dangerous for the patient and puzzling and instructive to the attendant. It was reported to the Marion County Medical Society, October 16, 1889, with presentation of the specimens. The latter are now in the museum of the Indiana Medical College.

EXPECTANT TREATMENT VERSUS LAPAROTOMY FOR GUNSHOT WOUNDS OF THE ABDOMEN.

By R. W. KEENE, M.D.,

VERSAILLES, KY.

In giving the three following clinical histories it is not my intention either to contravert or to affirm the necessity for immediate laparotomy in gunshot wounds of the abdomen, but simply to state the facts as they have recently occurred in my practice, more especially as I have just seen extracts from two papers read before the American Medical Association at Nashville, by two distinguished gentlemen, viz., Dr. Barrow, of Lexington, Ky., and Dr. Manley, of New York, in which they take diametrically opposite views as regards the necessity for immediate laparotomy, and as to results of operation. I think it the more important as the tide of opinion seems to be reversing in regard to the necessity of opening the abdomen in all cases of shot wounds of this region, whether there be urgent symptoms or not. These are the only cases of shot wound I have had recently—all treated without operation—all recovered.

Case I.—M——, aged twenty, was shot, June 26, 1888, at noon, with a 32-calibre pistol-ball, entering the abdomen two inches to the left of, and just below, the level of the umbilicus. Dr. Smith, the attending physician, called my friend Dr. Crenshaw and myself in consultation at 10 o'clock A.M. of the 27th. Found the patient with pulse of 88, temperature 101°F., suffering considerable pain. We could find no evidence from shock, etc., of the intestines having been wounded. Advised hypodermic of morphine and promised to see him the next day. 28th: Found him resting comfortably, a little vomiting of green matter, probably from a little local peritonitis, but no marked distress; slight tympanites. Advised waiting, but to send messenger if any urgent symptoms arose. 29th: Messenger came saying that patient was vomiting green material, and to be prepared to operate. When we arrived (distance eight miles) the bowels had moved freely and all symptoms were relieved, hence we advised letting well enough alone, and in two weeks he was up and about.

Case II.—W. L——, aged eleven, was shot, August 3, 1888, with 32-calibre pistol, at 7 o'clock P.M. Saw him at 9 o'clock of the same evening. Ball entered the abdomen two and one-half inches to left of, and one inch below, the level of umbilicus. No shock, some pain, for which gave morphia. Dressed external wound with iodoform and lint. Left, promising to return in the morning.

August 4th, 9 A.M.—Found him with temperature 100° F., pulse 90, resting comfortably under small doses of morphia. Retention of urine, for which used catheter. 6 P.M.: Condition about the same.

August 5th, 9 A.M.—Condition unchanged, had to use catheter and morphia twice daily. 6 P.M.: Resting comfortably.

August 6th, 9 A.M.—Some tympanites; temperature 102° F., pulse 112, no special distress; attributed the rise in temperature to local peritonitis. Ordered a saline purge, and follow with enema, and send in haste for me if green vomiting should commence. At 2 P.M. messenger came with report that he had vomited one pint of green matter. I hurriedly went out a distance of five miles and found that bowels had not moved. The case now looked serious; consequently I posted a messenger in haste for two of my colleagues to assist in the operation, as it now seemed inevitable that it must be done. While waiting for assistance repeated saline and enema, and had the satisfaction to get a copious discharge from the bowels, and by the time assistance arrived the temperature had fallen to 100° F., and pulse to 100, and all alarming symptoms gone; but, fortunately, we had lost the opportunity for laparotomy. In four days more I ceased my visits, though the father had to use the catheter some days longer. Recovery.

Case III.—G. H——, aged nineteen, was shot, June 3, 1890, with 22-calibre pistol at 9 P.M. My colleague, Dr. Shields, attending, called me in consultation immediately after the shot. Found the patient lying on the floor of the doctor's office with a bullet-hole in the abdomen, one inch to the left of umbilicus and on a level with it; ball entered the cavity; patient composed; pulse 64; no shock; no pain of consequence. Advised dressing the external wound antiseptically and remove him carefully to his home and await developments; be prepared to operate on first symptom of wound of intestine.

June 4th.—Saw him again. Rested well during the night; no pain except a sense of weight in the abdomen; no evidence of a solution of continuity of the abdominal contents. I advised further waiting, contrary to advice of other professional friends. His temperature this day was 100° F., pulse 72, and this was the highest point reached. I did not see him again; but he has recovered, and is now, fifteen days after the accident, walking about town, and we have, fortunately, missed another laparotomy.

I do not pretend that I was justifiable in the course pursued and advised in these three cases; but I believe in future I would do likewise if my judgment told me, as it did in these, that there was no wound of the intestine.

Nitrate of Potash in Chronic Malaria.—Dr. J. D. Hunter and other Texas physicians recommend highly nitrate of potassium in chronic malaria (*Daniel's Texas Medical Journal*). In combination with iron and quinine, nitrate of potash has long been used by Southern physicians for this purpose.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 19, 1890.

THE HYDROPHOBIA SCARE.

ONCE upon a time when Death and Pestilence bargained for human lives, it was agreed that an equal division of spoils should be made. At the end of the epidemic, Pestilence complained that Death had taken more than his share, while Death maintained in turn that more than the agreed number were stricken by Pestilence. The quarrel was, however, soon ended when Fear appeared to explain that it was he alone who had been accountable for the discrepancy, not only in increasing disease but in swelling the death-rate. In fact his record was greater than that of Pestilence and Death combined. Moral: Give Death and Pestilence a reasonable chance on a fair field. Although we do not wish to dignify the present hydrophobia scare by calling it an epidemic, the fear of it which has been scattered so widespread over the land has placed it on the top wave of general discussion. Fear has at present everything to himself and it is time to call a halt. As we have said before, we do not wish to question the scientific motives of the gentlemen who manage hydrophobia institutes, but we doubt the good results that are said to have been obtained by them. In attempting to prove the truth of the theory of preventive inoculation they are starting from an airy nothing and striving to work down to solid facts. But the real bottom is a great way off. There is too much of partial and willing testimony concerning the question at issue to give it any scientific value whatever. Logically speaking, everyone must admit that it is exceedingly hard to prove how you may prevent what may never happen, or in other words, how you can prove that a thing which at best very rarely happens is prevented from happening at all by the use of a supposed preventive. In attempting to argue the question we are swinging around a circle of negative propositions.

Everyone who has studied the subject acknowledges that hydrophobia, if, indeed, it exists at all in the human subject, is at least a very rare disease. Compare this fact with the almost countless number of persons who are bitten from year to year by dogs supposed to be rabid. If statistics were collected on this point the results would prove that there is no more apparent relation of cause and effect between the bite of a dog and hydrophobia than between an accidental sneeze and a stroke of lightning.

And yet what do we read in the daily papers in connection with the present hydrophobia scare? Judging from these accounts it would be fair to assume that the community was as much exposed to hydrophobia as to typhoid fever, pneumonia, or any other of the ordinarily common diseases. Scarcely a day passes that some new cases of dog-bitten patients do not present themselves in the terrible plight of fear of a horrible death. It does not make any difference apparently whether or not it is known that the dog was mad, the patient gets the benefit of the doubt, and the so-called preventive does its perfect work. And the cry is still they come.

Scientifically speaking it is still to be proven that this inoculation of hydrophobic virus has ever prevented an attack of hydrophobia or modified its course. And where are the cases of hydrophobia said to be dying or dead throughout the country? What has become of those which have been abandoned to their fate as beyond the reach of the preventive treatment? Surely such are interesting enough to warrant detailed records in scientific journals. And yet we never hear of them except in sensational reports connected with the booming of the inoculation theory, and the popularization of special hospitals in which the alleged wonderful treatment is practised. We say this in no captious spirit of criticism, but in the true interest of hundreds who may become unnecessarily alarmed and may be in despair of timely assistance. All things being equal, they can from the present outlook afford to take the chances of treatment by the family physician. We can certainly hold him responsible for any marked increase in the mortality statistics from this dreadful disease in case he fails in the performance of his duty. Then again, if any of the thousands of physicians may meet with a single case in a lifetime of practice we may obtain some impartial records of the etiology, symptoms, diagnosis, pathology, and treatment, and thereby obtain a much needed natural history of hydrophobia. Science always favors inquiry and honors the conscientious investigator. All praise, then, to the man who has done the most work in that direction. His theory is an admirable one, but it is still much too far above ground. The house is on stilts instead of solid rock. Until the foundation is more surely laid the country is reasonably safe. The man, woman, or child who may be bitten by dog, cow, horse, or hen may still live; at least, he or she has a much better chance for so doing than either of the offending animals, even without further inoculation.

NOT AN EXAMPLE TO BE FOLLOWED.

ABOUT once a year, and oftener in good seasons, our esteemed contemporaries on the other side of the water raise their voices with one accord in praise of His Royal Highness Duke Carl Theodore, of Bavaria. The present is one of these joyful occasions when the pæans begin to resound, and the following is a specimen of one of the more moderate of them, which appeared recently in an English journal: "From Meran we hear that H. R. H. Duke Carl Theodore, of Bavaria, has resumed the gratuitous treatment of eye diseases among the Tyrolese poor, and that during the last four weeks he has carried to a successful issue 170 operations, of which 53 were for cataract. His Royal Highness is a duly qualified practitioner of the Munich school, whose curriculum he supplemented by the cliniques of Vienna and Berlin; and it is as no mere amateur, but as a surgeon whose skill goes

hand-in-hand with his enthusiasm for the healing art that he attracts to his hospital at Meran not only the Austrian, but the Swiss and the Italian poor, who travel long distances to benefit by his humane tendance and successful treatment."

There is nothing offensively adulatory in this, as there is in many of the notices concerning the royal doctor, yet there is a tone of commendation in it which would perhaps be less evident were the paragraph about some ordinary mortal of obscure birth. It is very well to praise industry and to laud one who, having the choice, yet prefers work to idleness. But industry is not the only virtue in this world, and the unreasoning practice of it is by no means always to be commended. The well-to-do have other duties toward their fellows than mere charity, as this word is generally understood, and their chief duty is to keep out of the way of those who must work to live. They need not necessarily be idle—there is plenty of unremunerative work that cannot be done by the poor man, and which commends itself especially to the man with leisure and means at his command. Let him work, if he will, and all honor to him for so doing, but let him not take work, paying work, from others who must have it or starve. The continual cry is that the medical profession is overcrowded, and the complaint is only too well founded on fact. The supply is far greater than the demand, and it is impossible for all to get enough to do to live decently. Such being the case, of course every new worker takes away something from others, and something which most of them can ill afford to lose, and unless he must work to live we hold that he does wrong to his fellows in practising medicine. He is injuring his colleagues in the same way as the dispensaries of evil odor. It makes no difference to say that he loves the practice of his profession, and therefore has a perfect right to continue in it. This is the argument of the selfish man, and not of the one who thinks of the needs of others. The duty of the rich man is not to work in overcrowded fields where those of slender resources must find their living, but rather, if he will labor (for which determination there can be nothing but praise), to occupy himself with some useful work for which there is no remuneration of a material kind. Let him work for fame, and let no one begrudge him the fame that his industry may win for him, but let him not take the bread out of the mouth of his less fortunate brother.

THE TREATMENT OF DETACHMENT OF THE RETINA.

THERE is no greater opprobrium of ophthalmology than that of the treatment of detached retina. Despite every attempt at relief which medicine or surgery could devise, the disease is almost always unaffected, and more or less blindness results. Rest in bed, pilocarpin, and antiphlogistics have been the chief resorts, but these offer little hope. A great many surgical measures have been attempted, but most ophthalmologists view them with distrust.

The disease is caused by traumatism, progressive myopia, and other causes which are unknown. Leber and Schoeler hold that there is always a tear in the retina at first, and it is believed that some inflammatory process with exudation is present between the retina and choroid.

Among recent methods of treatment, Galezowski has asserted that good results follow the passing a catgut thread through the detached portion. Dr. S. L. Phillips, in the *Atlanta Medical and Surgical Journal*, calls attention to the fact that, in making observations upon rabbits' eyes of injections of various antiseptics to test their value in septic choroiditis, Schoeler had results which were such as to make him think that this treatment might be of use in retinal detachments. After sundry experiments with a number of drugs, tincture of iodine was finally settled upon as the only preparation of any real use in this trouble. It was sufficiently strong to do the work, and not too irritating. It was injected through the sclerotic, choroid, and retina into the vitreous chamber, in preference above the detachment and near the supposed opening. This was done with a hypodermic syringe, but with a curved instead of a straight point, and from 2 to 6 drops injected. The vitreous is compressed, the retina shoved toward the choroid, and any old adhesions torn up. The fluid, now diluted, passing through the rent, comes in contact with the other surface of the retina, producing adhesive inflammation; the retina being then in contact with the choroid, becomes firmly attached. The earlier these injections are undertaken the better; for when the retina becomes wholly detached from the choroid, being fast only at the optic nerve and ora serrata, or when degenerative changes have taken place, it is too late for any treatment. Of course, after this operation, the patient is put to bed, with compress bandage over the eyes, and kept there one or two weeks. Under these circumstances a light or milk diet is preferable. If there is much pain, which is likely, morphia, hypodermically, can be given. The process of healing is watched by the use of the ophthalmoscope.

Schoeler reports five cases in detail. In these five cases the results have been most satisfactory.

Unfortunately for the promise of this method, Gelpke reports a most disastrous result following its use in one case. The injection of three drops was followed by a purulent choroiditis. This certainly need not follow a scrupulously careful antiseptic injection, but it shows the dangers of the practice.

THE CONTAGIOUSNESS OF PHTHISIS.

AT the present time, when so much is being written about the contagiousness of phthisis, it is well occasionally to hear the other and the older side. Dr. A. Haupt, of Soden, has recently written a monograph in which he has collected many facts to support the view that, after all, it is the inherited tendency or "soil" which is the important factor. He quotes from the Report of the Collective Investigation Committee in respect to the Brompton Hospital, in which the danger of infection is declared to be utterly improbable. Celli, Guarneri, Aufrecht, and others, are of nearly the same opinion. Robertson found that in at least 80 of 100 married couples in which the husband or the wife was consumptive, the other party did not become so. Leudet observed that, out of 112 widows and widowers of persons who died of consumption after illness varying from one to twenty years in duration, 105 remained perfectly healthy. During the fourteen years of Dettweiler's work as physician in the Consump-

tion Hospital at Falkenstein, there has not been a single case of infection among the attendants, some of whom were for seven years in constant contact with patients who were dangerously ill. The author quotes the following words of Professor Leyden: "Immediately after the discovery of the tubercle bacillus there was a tendency to attach much more importance to contagion than before, but further observation has shown that it does not play so very great a part, and that the majority of cases are due to heredity." Of 680 Italian physicians, 59 declared for contagion, 124 against it, and 497 mainly for heredity. In England 792 out of 1,078 declared against contagion. Dr. Haupt reports his own experience at Soden thus: Among the 1,500 inhabitants of the place there are 101 who let lodgings. In most of the houses the wives, with sisters or daughters, serve and tend the tuberculous patients who come for treatment. In many houses servant girls from the neighboring villages, hired for the summer, help, making the patients' beds, cleaning their rooms, beating the carpets, removing the sputum—these occupations, so closely connected with the danger of infection, are, among others, the tasks of these persons; and it must be added that they prefer the severest cases, because, as more help is required, the remuneration is higher. In winter the members of the landlords' families occupy the rooms in which generally the most severely affected patients have laid—the rooms on the ground floor. Between 1855 and 1888, 48 of the 238 members of such families died, 10 of them of tuberculosis. In 6 of these 10 cases heredity was demonstrable, and the remaining 4 were due to colds and external causes. Of the 415 servant girls, 17 died, 5 of them of tuberculosis, also demonstrably due to other causes than infection. Within thirty years, then, among 653 persons, most of whom were for several summers with and in attendance on the patients, there were 15 deaths from tuberculosis, not caused by infection. The same proportion prevails among other persons in close contact with consumptive patients, attendants, washerwomen, etc.—*Lancet.*

News of the Week.

American Public Health Association.—The Eighteenth Annual Meeting of the American Public Health Association will be held at Charleston, S. C., December 16, 17, 18, and 19, 1890. The Executive Committee have selected the following topics for consideration at said meeting: 1, "Sanitary Construction in House Architecture," *a*, Heating, *b*, Lighting, *c*, Drainage, *d*, Ventilation; 2, "Sewage Disposal;" 3, "Maritime Sanitation at Ports of Arrival;" 4, "The Prevention and Restriction of Tuberculosis;" 5, "Isolation Hospitals for Infectious and Contagious Diseases;" 6, "Establishments in Favorable Climates for Persons having Tuberculous Predispositions," *a*, Schools for Children and Adolescents, *b*, Sanatoria, *c*, Permanent Residence; 7, "Papers on Miscellaneous Sanitary and Hygienic Subjects." All papers will be received by the Executive Committee subject to the requirements of the By-Laws. Preference will be given, however, to papers upon the subjects selected by the Committee in making up the daily programme of the meeting. All persons who propose to present papers at the next meeting of the Association will be governed by the following By-Laws of the Executive Committee: "4. All papers presented to the Association must be either printed, type-written, or in plain handwriting, and be in the hands of the Secretary at least twenty days prior to the annual meeting, to insure their critical examination as to their fulfilling the requirements of the Association. 5. If any paper is too late for critical examination, said paper may be so far passed upon by the Executive Committee as to allow its reading, but such paper shall be subject to publication or non-publication as the Executive Committee deem expedient. 6. All papers accepted by the Association, whether read in full, by abstract, by title, or filed, shall be delivered to the Secretary as soon as thus disposed of, as the exclusive property of the Association. Any paper presented to this Association and accepted by it shall be refused publication in the "Transactions" of the Association if it be published in whole or in part by permission or assent of its author in any manner prior to the publication of the volume of "Transactions," unless written consent is obtained from the Publication Committee. 7. Day papers shall be limited to twenty minutes, and evening papers to thirty minutes, each." Invitations extended to individuals to prepare papers for the Association do not imply their acceptance by the Committee, merit alone determining that question. All communications relating to local matters should be addressed to H. B. Horlbeck, M.D., Chairman Local Committee of Arrangements, Charleston, S. C. Another circular will be issued before the meeting, giving transportation rates, hotel rates, etc. Blank applications for membership can be obtained by addressing the Secretary, Dr. Irving A. Watson, Concord, N. H.

Death of Dr. Charles L. Allen.—Dr. Allen, of Rutland, Vt., one of the most prominent physicians of the State, died suddenly on July 2d. Dr. Allen was born in Brattleboro, on June 21, 1820. He was graduated from Middlebury College in 1842, and from the Castleton Medical College in 1846. The deceased was a professor in Castleton Medical College before the war and afterward became president of the institution. He left there, however, to accept the professorship of Civil and Military Hygiene in the University of Vermont at Burlington. While there he went to the war and was appointed a member of the examining board of brigade surgeons. In 1857 he was Acting Professor of Chemistry and of Materia Medica in Middlebury College. Dr. Allen was secretary of the State Board of Health, and had been connected with the board since its organization; he did a vast amount of work as secretary, for which he received no compensation. He edited the *Sanitary Visitor*, and did most valuable work in the interest of the health of the State. The deceased was the first president of the Rutland Medical Club, an honored member of the Vermont State Medical Society, of the American Medical Association, and of the American Academy of Medicine.

Mushroom Poisoning is said to be of very frequent occurrence among the Italian peasants, who are very fond of mushrooms, but seem unable to distinguish between the edible and poisonous varieties.

Morphine as an Antagonist to Atropine.—A case of considerable interest occurred at Chadarghat in Hyderabad recently, and is reported in the *Medical Record* of Calcutta. A medical student, who was a great sufferer from neuralgia, for which he was accustomed to take antipyrine, went to indulge in his customary dose, but hit upon the wrong bottle and took six grains of atropine instead. In a few moments he became unconscious and fell. He was seen by a brother medical student, who instantly ran off and called Surgeon-Major Edward Lawrie. An emetic was speedily given, and the stomach-pump used to wash out the contents of the stomach. The patient, however, seemed to be rapidly sinking from the effects of the drug. The pupils were dilated to their fullest extent, there was foaming at the mouth, stertorous respiration, and a rapid intermitting pulse. The condition seemed hastening toward the end, when Dr. Lawrie thought he would resort to the antagonistic effects of morphine, and injected one grain of this drug subcutaneously, with no apparent effect. He then injected another grain, but with no decided result. The patient, though still alive, seemed hovering in the balance between life and death. From eight o'clock in the morning till three in the afternoon artificial respiration was resorted to with varying intervals of rest. Dr. Lawrie now determined to try the hypodermic injection of a third of a grain of morphine, and this says *The Lancet*, seemed to be the determining antidote, for in an hour the pulse improved, the breathing gradually resumed its normal standard, and consciousness returned. Since it was seven hours at least before the "determining" antidote had its effect its specific action may be questioned.

The Doctor Victorious.—A suit for malpractice was brought against Dr. McKinnon, of Selma, Ala., about a year ago, the case being one of fracture. A verdict was promptly rendered in favor of the defendant.

Next International Congress of Hygiene.—The Lord Mayor of London issued invitations for a public meeting at the Mansion House on July 3d, on behalf of the International Hygienic Congress, which will be held next year in London. Similar congresses have been held in different continental cities, the last at Vienna, under the presidency of the late Crown Prince of Austria. Already the Universities, the Colleges of Physicians and Surgeons, and the various learned societies have appointed delegates, and a large representative committee is being formed for making the necessary arrangements. The Congress itself will be presided over by the Prince of Wales. We sincerely trust that the Lord Mayor will be well supported, and that every effort will be made to give a cordial welcome to the many distinguished foreigners who will attend on the occasion if the Congress is held.

The International Medical Congress.—Besides the deputation of French military doctors, a deputation of three eminent men of science, appointed by the Minister of Public Instruction, will take part in the International Medical Congress in Berlin. Their names are Professors Léon le Fort, Bouchard, and Charles Richet. Professor le Fort's name is a specially honored one in Germany, for he has repeatedly defended the German surgeons from the unjust accusation that they neglected the wounded French prisoners of 1870–71, and has at all times followed the progress of medical science in Germany with warm sympathy, and reported it to his countrymen. The official representatives of the United States at the Congress will be Mr. C. H. Alden and Major S. Billings. At the suggestion of the Committee of Organization a Ladies' Committee has been formed, whose main task it will be to make the stay in Berlin as pleasant as possible for the wives of foreign medical visitors.—*Lancet.*

The Harper Hospital Bulletin is the name of a new bi-monthly periodical published at Detroit and devoted to hospital work.

Cures for Neuralgia of the Head.—An English physician has recently asserted that headaches and neuralgia could be stopped by blowing a solution of salt up the nose. A Swiss physician, Dr. Naegely asserts that he can cure neuralgia of the trigeminus by pressing up the hyoid bone.

A New Hospital for Berlin.—At a meeting of the Berlin Municipal Council on June 12th, it was decided that a convalescent home for lying in women should be established at the expense of the city. A sum of $35,000 was voted for the purpose.

The Increase of Insanity in Berlin has made it necessary that a new public lunatic asylum should be established. The building, which is to accommodate one thousand patients, will be situated in the easterly suburb of Lichtenberg. The City of Berlin already maintains an asylum with about twelve hundred inmates at Dalldorf.

The University Medical College of this City and the Bellevue Hospital Medical College announce that, beginning with 1891–99, three courses of lectures will be required for graduation.

Latin should be Used.—The *Provincial Medical Journal* agrees with us in regarding Latin as the only language which can be adopted as the universal medium of communication in scientific assemblies. The question of a universal language of science has, it says, been frequently discussed, and it will probably be ventilated again at the Congress. French is the language of diplomacy, and the French therefore urge their claim to have French chosen as the medium of communication between the learned men of different countries. We can hardly expect the Germans to accept this proposition. English has a claim for some consideration; but France and other foreign countries will put their veto upon our claim. Volapük has now a strong following, and this strange amalgamation of tongues offers itself as the solution of a difficulty. Considering the difficulties of the new language, we can hardly favor its pretensions. If we really require a special tongue for science, we should fall back upon the Latin. We have here a language with a history and a literature, and if it could be established that Latin was to be in the future the means of communication between learned men, then Latin would be taught in the schools of the world in a much more rational way than it is at present, and still more those who intend to enter the medical profession would have to acquire a much wider acquaintance with its literature than is expressed by the first two books of Virgil or Cæsar, which represents at matriculation the acquaintance of the candidate with the *literæ humaniores.*

Small Infants.—Dr. Cordes, of Geneva, writes to the *Lancet* that a case of twins occurred in 1858 among his own relatives, one of which weighed only six hundred and twenty-five grammes (25 oz.), the other weighing just twice as much. No couveuse was employed, but both are now living.

A Doctors' Club is to be established in Oshkosh, Wis. There will be meetings at stated intervals for the discussion of medical questions, but in addition a club-house will be built where the members can come together informally at any time and meet each other socially.

Testing the Legality of Vivisection.—Two Philadelphia physicians were recently arrested on a charge of cruelty to animals, the charge being based upon the fact that they were in the habit of practising vivisection on dogs in the course of their experiments.

Codein.—According to Lowenmeyer (*Deutsche medicinische Wochenschrift*, No. 20, 1890), codein is very little employed in Germany, notwithstanding the encomiums which it receives from physicians elsewhere and especially from the French. He therefore recently instituted an extensive series of observations in Jacobson's service at the Jewish Hospital in Berlin. Some five thousand doses of the drug were given to about four hundred patients, some of whom took it for weeks, and others for months; yet in no case did he observe any untoward results. He therefore recommends its use in place of morphine, rating it as a narcotic of somewhat lesser intensity than the latter, but on the whole superior, because of its freedom from danger. He especially endorses Dr. Lauder Brunton's assertion of the peculiar applicability of codein to the relief of painful affections of the abdomen. Gastralgia, colic, and the various visceral neuralgias seemed peculiarly amenable to its influence.—*Medical News.*

Local Tuberculous Infection.—An accident which recently befell Dr. Gutzmann, of Berlin, may serve as a warning to surgeons and pathologists to be careful in handling tuberculous tissues. On February 19th, while he was making a post-mortem examination on a patient who had died of acute miliary tuberculosis, the nail of his right middle finger was slightly raised from the matrix. He felt a little pricking at the tip of the finger, but could see no wound. After washing it in sublimate solution and alcohol, he forgot all about it, and used the finger in percussion without inconvenience. On March 20th it again became painful, and a tiny abscess was found under the nail. This was opened and the pus examined by Ehrlich's method, when three tubercle bacilli were discovered. The preparation was shown to several practitioners, who all identified the bacilli. The abscess was then scraped out and disinfected with alcohol. Up to the present there has been no lymphangitis or glandular enlargement, and no rise of temperature. Dr. Gutzmann regards the case as an example of local tuberculous infection.—*British Medical Journal.*

Thyroid Grafting in Myxœdema.—Mr. Horsley's suggestion that myxœdema might be treated by transplantation of a piece of thyroid gland from an animal to the human subject has lately been carried into effect by Professor Lannelongue, of Paris. The patient, a female cretinoid idiot, aged fourteen, presenting the usual signs of myxœdema, had a piece of the thyroid gland of a sheep implanted into the subcutaneous tissue of the left side of the chest. The wound closed over the graft, but sufficient time has not yet elapsed to allow a judgment to be formed as to the results of the operation on the constitutional condition.—*British Medical Journal.*

Bismarck's Regimen.—The details of Prince Bismarck's present dietetic regimen, says the *British Medical Journal*, may be interesting to those interested in the treatment of obesity. He says: "I am only allowed to drink thrice a day—a quarter of an hour after each meal, and each time not more than half a bottle of red sparkling Moselle, of a very light and dry character. Burgundy and beer, both of which I am extremely fond, are strictly forbidden to me; so are all the strong Rhenish and Spanish wines, and even claret. For some years past I have been a total abstainer from all these generous liquors, much to the advantage of my health and my 'condition,' in the sporting sense of the word. Formerly I used to weigh over seventeen stone. By observing this regimen I brought myself down to under fourteen, and without any loss of strength—indeed, with gain. My normal weight now is one hundred and eighty-five pounds. I am weighed once a day, by my doctor's orders, and any excess of that figure I at once set to work to get rid of, by exercise and special regimen. I ride a good deal, as well as walk. Cigar-smoking I have given up altogether; it is debilitating and bad for the nerves. I am restricted to a long pipe, happily with a deep bowl, one after each meal, and I smoke nothing in it but Dutch Knaster tobacco, which is light, mild, and soothing. Water makes me fat, so I must not drink it. However, the present arrangements suit me very well."

A New Mixture for Use in Local Anæsthesia.—Dr. A. Dobisch, of Zwittau, has used, for the purpose of producing local anæsthesia, a spray, with Dr. Richardson's ether spray apparatus, composed of ten parts of chloroform, fifteen parts of sulphuric ether, and one part of menthol. After one minute's application of this spray complete anæsthesia of the skin and neighboring tissues were obtained, which lasted for from two to six minutes, and sufficed for the performance of such minor operations as opening abscesses of the cervical glands, incising a deeply seated whitlow, and the excision of an epithelioma of the nose. In all the cases in which he employed the spray above mentioned the wounds healed quite satisfactorily.—*The Lancet.*

No Hospital for Infectious Diseases in Chicago.—Chicago is to have the World's Fair. It has over a million population; its streets are 1,386 miles long, and its street-car lines 637 miles long. Its parks cover 2,038 acres, and 850 trains arrive and depart daily; yet there is not a hospital in the metropolis where a case of diphtheria or scarlet fever can be taken.—*N. A. Practitioner.*

The Medical Department of the Newberry Library, of Chicago, has fairly begun its existence. It has on its shelves two thousand volumes donated by the Medical Library Association, and is preparing to order a large invoice of the principal medical serials. Adjoining this department the trustees have provided a large room which they will probably offer for society meetings.—*N. A. Practitioner.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Stated Meeting, May 20, 1890.

FRANCIS DELAFIELD, M.D., CHAIRMAN.

The After-treatment of Obstetric Cases.—DR. W. B. WOOD read a paper on this subject. At the outset he said that he laid no claim for originality in the views that he was about to express, but at the same time the method of treatment which he advocated differed sufficiently from that commonly adopted, he thought, to render what he had to say of some interest.

For some years past it had been a matter of observation to him that the number of cases of laceration of the cervix was really much greater than would appear from any statistics that had ever been published on the subject. In fact, he now believed that at least slight laceration of the cervix takes place in every woman who is delivered of a child. The reason why many of the cases escaped notice was because nature acted so promptly and efficiently, that the slighter degrees of laceration were repaired before the time came when the accoucheur ordinarily made his examination of the parts.

During the past five years he had worked on the theory that, if the slight forms of laceration were so ready to heal without any attention on the part of the physician, the severer ones would spontaneously heal in the same kind manner if the proper conditions for the accomplishment of this purpose were afforded. Omitting the histories of certain illustrative cases which he had selected from his practice, he went on to say that in his hands not only in no case had a fresh laceration remained unhealed, but in many older cases successful repair had taken place without any operative interference whatever. The importance of the method in question in preventing permanent trouble could be readily appreciated.

The best skill could not prevent, but could only modify and control, laceration of the cervix. It had often been alleged that there was no more reason why parturition should be attended by such accidents, than was the case among savage tribes; but such a statement was absurd. The fact that was pertinent to the question at issue, and that was quite sufficient to explain the results commonly met with, was that, as civilization advances, the cranium increases in size, while the pelvic diameters diminish.

Outside of laceration of the cervix, there was no other condition following parturition which occasioned so much trouble as arrested involution. Five years' experience in the matter, however, had convinced him that this would yield to the same treatment. According to the best authorities, it required from six to ten weeks for the uterus to return to its normal size and weight, and from three to four weeks for the vagina, and from six to twelve weeks for the relaxed uterine ligaments and appendages to resume their normal condition after confinement. Yet ordinarily it was in the second week, while involution was still far from completion, and any lacerations that might have been caused during labor were still unhealed, that the woman was allowed to get up and go about. In consequence, the uterus dropped downward and tipped out of its normal position; and under these circumstances it was not to be wondered at that the health of the patient became permanently impaired. The evils resulting had been admirably summed up by Emmett in his work on "Diseases of Women."

From his observations, he was firmly convinced that these evil results could be avoided by the observance of proper precautions both before and after the puerperal period. Before her confinement the patient should be educated up to a right appreciation of the dangers that were liable to result therefrom, and of the appropriate means for escaping them. It was a fact that, up to the present time, the human uterus had never become thoroughly adjusted to the upright position, and that it could be said to be perfectly held in place only when the woman was in the genu-pectoral posture, or that of the quadruped. Under the most favorable circumstances it could be readily seen, therefore, how easy it was for the organ to slip out of position.

The treatment which he practised and advocated after ordinary labor was as follows: He kept the patient in bed for four weeks, and during fourteen to twenty-one days of this time she was to be kept strictly on her back. At the end of twenty-one days he made an examination, the patient being placed in the Sims position. Then hot vaginal injections were employed, after the manner of Emmett, if no lacerations were found to remain. If there were any lacerations, the injections were to be omitted, as tending to interfere with the healing process. At the end of four weeks, if there were no abnormal conditions present, the patient was permitted to get out of bed; but before she did so she was placed in the genu-pectoral position and the uterus was carefully supported, before and behind, by pads made of cotton saturated with borated glycerine. The supporting pads, renewed at sufficiently frequent intervals, were to be worn for five weeks more. Finally, the physician was to make an examination of the patient once a month for a year following her confinement, in order to see that no displacement of the uterus or other abnormal condition had resulted.

In hospital and charity work such a course was impracticable; but in private practice it should be insisted on, and it would readily be consented to by the patient if she were properly educated up to it. There were few women to be found who would not willingly submit to any course of treatment which would relieve them from the necessity of an operation; and if, in the case of any patient suffering from a laceration of the cervix resulting from a former labor, it was represented to her that, with the observance of proper care after her next confinement, the trouble could be obviated without a resort to operative measures, the chances were that she would most cheerfully consent to the treatment prescribed.

Dr. Wood then referred to the matter of lactation, and said that while nursing undoubtedly furnished a favorable stimulus to the uterus while undergoing involution, in many cases the advantages arising from this were more than counterbalanced by the evil effects of the drain upon the general system caused by it; and hence, in order that the woman might be afforded the most satisfactory conditions for a complete restoration to health after her confinement, it was often necessary that the infant should be weaned at an early period. With our present improved facilities for artificial feeding, this was attended with much less risk to the child than was formerly the case.

In conclusion he said that within the past years the advances made in obstetrics and gynecology had resulted in an appreciable decrease in mortality from childbirth, as regards both the mother and the child; and it only remained that we should adopt an after-treatment in cases of midwifery which would prevent subinvolution and permanent lacerations.

The Gross Anatomy of Chronic Pulmonary Consumption in Relation to Diagnosis and Prognosis.—DR. J. WEST ROOSEVELT read a paper on this subject. He said that the great importance of making an early diagnosis and correct prognosis in phthisis was his only excuse for presenting this paper. While the evidence of the existence of tuberculosis afforded by the discovery of the Koch bacillus in the sputa was naturally absolutely unassailable, the absence of the bacteria must always leave a doubt in the mind as to the presence of the disease. There were so many important precautions to be observed, however, before the absence of bacilli could really be held to exclude consumption, that it was necessary to be very careful in estimating the value of negative observations.

To exclude consumption by negative results in searching for bacilli it was necessary, first, that the examination be made by an expert with a good microscope and good dyes; second, that a sufficient quantity of sputum be obtained; and, third, that a very large number of observations, extending over a considerable time, be made. By the term expert he meant a person trained by long practice to make the observations. In all cases of suspected tuberculosis, however, the element of time was a very important one, and it would not do to waste too much valuable time in examining the sputa. It was always to be remembered that it was not the bacilli in the sputa, but those remaining in the lungs, that were to be feared; and hence we should not give the latter a good chance to increase while we were looking for the former.

Having dwelt upon some of the points required for accuracy in making examinations of sputa, he said that it was natural that the results of the labors of both Laënnec and Koch should have been misjudged, especially in respect to their value as negative evidence. In each case their value as positive evidence had been enormous; the bacillus, so far as we know, affording absolute proof. Positive evidence was naturally that first sought. In the case of almost all important additions to scientific knowledge, the first general idea, after accepting the facts, was to see what they positively prove to exist. Long after this came the question of what they do not demonstrate; and of both Laënnec and Koch's discoveries it might be said, that their value of positive evidence was so great that their importance in excluding disease had been overestimated.

He next spoke of the clinical classification of cases based upon the gross anatomy of the lesions. In the present study, he said, we had nothing to do with the finer details of pathological anatomy. In order to understand his point of view, however, it was necessary to admit the following things:

1. The discovery of tubercle bacilli in sputum furnishes positive evidence of consumption, or of tuberculosis somewhere in the air-passages.

2. Chronic consumption of the lungs occurs sometimes in a form in which the lesions consist of more or less distantly separated small nodules, and sometimes in a form in which there is more or less widespread solidification of the lung. In either of these forms cavities may be found. In both the lesion first invades, in a large majority of cases, the apices of the lungs.

The anatomical classification thus adopted was of importance mainly for diagnostic and prognostic purposes, and did not pretend to histological accuracy. The first variety, the discrete, embraced those cases which Delafield had placed in the first division of the class designated by him as chronic miliary tuberculosis. It also embraced certain cases belonging to Delafield's second subdivision of chronic miliary tuberculosis, in which, besides tuberculosis, there is new fibrous tissue. In short, it was intended to mean any form of consumption in which the lesion is discrete and does not produce much solidification.

The second variety, the diffuse, for the purpose in hand, included all cases in which the lesion is such as to solidify considerable portions of the lung in mass. Certain cases of Delafield's second division of chronic miliary tuberculosis were for convenience embraced in it, just as certain lesions much more complex than simple tubercular inflammation were embraced in the discrete form.

The discrete form was very often observed, at least in New York. In it the nodules, varying in size, were separated by lung-tissue which was physically normal or emphysematous. When cavities resulted, in advanced cases, from the breaking down of the nodules, they were usually of small size; and solidification of a portion of the lung, resulting from the increasing number of nodules, occurred only late in the course of the disease. There were usually more or less bronchitis and pleurisy, and also some emphysema of the kind known as compensatory. He believed that dilatation of the air-vesicles and passages was caused by mechanical air distention, and it seemed very probable that the elasticity of a larger or smaller part of the pulmonary parenchyma was destroyed by the growth of new tissue, if the thoracic expansion caused a negative pressure in the parts not affected which was greater than normal. The fact that emphysema was frequently limited to those portions of the lung near the nodules was explained by the pleural adhesions, which caused that part to follow closely the movement of the nearest rib. A probable additional cause for the emphysema was obstruction to the circulation produced by the nodules. In certain cases, moreover, the tubercular process took place in lungs already emphysematous.

In the diffuse form the important clinical facts were, that consolidation occurred and produced, at a much earlier stage than in the discrete form, recognized physical signs, and that, in at least a large number of cases, the physical signs corresponded pretty closely to the patient's actual condition. The consolidation always, in his opinion, accompanied tubercular deposit, and the latter was always, as he also believed, the result of the growth of Koch's bacilli. The consolidated tissue consisted sometimes entirely of dense connective tissue. Sometimes patches of coagulation necrosis, diffuse tubercle, interstitial pneumonia, broncho-pneumonia, and peribronchitis were mixed in varying proportions in it. With this, as with the discrete form, there were usually bronchitis and pleurisy.

The clinical value of the classification temporarily adopted was, that it recognizes the existence of cases in which the physical signs have no relation to the extent of the lesion—cases, moreover, in which the bacillus is very likely not to be found at an early date in the sputa. Having further explained the reasons for the latter circumstance, he said that the discrete form furnished cases which were liable to be mistaken for primary tubercular disease of the larynx, for broncho-pneumonia, or for substantive emphysema. It has been Dr. Roosevelt's observation that in every case properly examined the tubercle bacillus has sooner or later been found; but in the meanwhile the diagnosis has often remained in doubt, and the discovery of the true nature of the disease has not infrequently come too late.

In the diffuse form, on the other hand, not only were the physical signs generally well marked, but the bacilli are apt to appear in the sputa at an earlier date, and also to be more abundant from the first.

Having described a supposititious case in which the physical signs were doubtful and the sputum scanty or absent, so that the bacilli were discharged in small numbers, if at all, he said that such cases were not rare, and the recognition of this fact seemed to emphasize what was probably the most important fact in connection with early diagnosis, viz.: Both physical signs and the negative evidence of the microscope are to be regarded only after careful study of the clinical history. Percussion, auscultation, and the microscopic examination might reveal nothing, yet commencing consumption might be safely assumed to exist from the evidence of the patient's history and general appearance.

The idea which he wished to convey was that cases may occur, and that not infrequently, in which tubercle bacilli cannot be discovered, and in which physical examination of the chest gives no abnormal signs, or very vague ones, yet in which it is the duty of the physician to make the diagnosis of consumption and to take proper measures for treatment, no matter at what cost. In the class of cases under consideration the chances of consumption being the trouble were so strong, that the physician should risk his own reputation and perhaps put the patient to great inconvenience and pecuniary loss, in order to save the life of the latter.

In speaking of the relation of the anatomical conditions to the physical signs, he said that in the discrete lesion there

might at first be nothing abnormal about the lungs, except a few small scattered nodules at or near one apex. In the great majority of cases, however, pleural adhesions existed from a very early period. With the few scattered nodules alone there would, as a rule, either be no physical signs, or these would be very vague and untrustworthy. The pressure of pleural adhesions sometimes gave rise to special signs, and sometimes did not. In certain cases it seemed quite possible that they cannot show so-called cog-wheel or wavy inspiration; and in others they might perhaps produce fine dry or moist râles. Sometimes also they seemed to produce friction, stretching, or tearing sounds. In early cases the adhesions were so often near the summit of the lung (where relatively little gliding motion of the pleura took place), that it was easy to understand how frequently it was impossible to demonstrate their existence during life.

It was not clear to him, however, why many signs attributed by a number of observers to pleuritic adhesions should really be caused by them. Why, for instance, the type of subcrepitant râle, sounding like the bursting of fine bubbles, should ever be produced by the stretching of tissue, moist or dry, it was difficult to explain. It was easy to say, and it at first seemed plausible, that an increase of serum in the pleural adhesions would produce this sound; but we did not positively know that this condition ever did actually give rise to it.

Having spoken of the mechanical results of pleural adhesions, so far as the lung and chest movements were concerned, he said that in spite of very widely distributed and firm adhesions, it was possible for a lung seemingly to do its work as well as usual, and no symptoms whatever might indicate firm union between the pleural surfaces over the entire lung.

If, in addition to the nodules, there was enough bronchitis signs of this alone might be found. Signs of bronchitis with or without emphysema, upon one side of the chest, could as a rule be regarded as valuable evidence of consumption, since bronchitis confined to one side probably never occurred unless there was some local cause.

When the nodules became sufficiently numerous to crowd one another pretty closely, the lung was practically solidified, and the signs became those of consolidation. In such instances, however, the disease was far advanced. It was evident that in this form the physical signs bore but little relation to the extent of the lesion. The diagnosis in early cases must be made without too much regard for the signs, and the same was true of the prognosis also. In the absence of bacilli from the sputa the patient's general condition and history must be the main guide.

Discussion.—Dr. J. S. Ely said that some months ago, a woman of thirty-five presented herself at the Roosevelt Dispensary, who complained of general weakness and loss of flesh and appetite. There was but little cough, and an examination of the chest was negative in its results. There was no harsh breathing, and practically nothing was heard in the lungs except an occasional râle. From the progressive emaciation and the general appearance of the patient he concluded that she was suffering from chronic miliary tuberculosis. She was placed upon creasote and cod-liver oil, and urged to go to the Adirondacks if it were possible for her to do so. It was impossible for her to leave New York, however, and she came regularly to the dispensary through the winter. She gained considerable in strength, and about a pound a week in flesh. About six weeks ago she was attacked with a severe pain in the left eye. Dr. Ely made an ophthalmoscopic examination, but not being able to discover anything abnormal, he sent her to Dr. Weeks, who reported that far down in the edge of the retina there were five miliary tubercles. He was very glad thus to have the diagnosis which he had made confirmed.

It seemed to him that the early diagnosis of tubercular disease of the lungs had come to assume a specially important aspect, in view of the now very generally recognized fact that many cases could be cured if they were taken in time. It was often said that Koch's discovery had added nothing to our knowledge of the treatment of phthisis; but there could be no possible doubt that it had already been of great practical service. The results of the experiments made by Dr. Trudeau on rabbits, he thought, were of the greatest possible value in this connection. While all the rabbits inoculated with tubercular virus which were confined in an unhealthy environment died, only one of the inoculated animals—six or eight in number—which were given the best possible environment died. An examination of the lungs of the rabbits which recovered showed that the tubercles had become encapsulated, and were thus rendered incapable of doing any further harm. In the light of such results it could readily be seen that it was of vital importance that we should be able to recognize the presence of the disease at the earliest possible moment.

Dr. F. W. Jackson said that while in some cases we had to make the diagnosis without the aid of physical signs, in others, on the contrary, the diagnosis was made on the physical signs alone, in the absence of any symptoms to guide us. A case in point was that of a young woman, twenty-two years of age, who came to the Roosevelt Dispensary on account of some of those vague feelings so common in females, and who was to all appearances in more than ordinarily robust health. Yet when he came to examine her chest (not because there was anything to direct attention to the lungs, but simply in accordance with the routine practice at the dispensary), he found to his great surprise that there was a cavity at the apex of one of the lungs. On inquiry he ascertained that there was no antecedent history pointing to anything but tuberculosis as the cause of the cavity. Afterward the patient's health gradually broke down, and the other lung became involved also. Here, then, was a case in direct contrast to that related by Dr. Ely; there being nothing but the physical signs to go by.

His observations had led him to believe that pleural adhesions were very frequently present without giving rise to any physical signs, and he thought this was not generally recognized. Another point not sufficiently appreciated, to which he desired to direct attention, was the fact that râles, due to whatever cause, were not constant. Thus, they might disappear and reappear while the patient was actually under examination. Two lessons might be drawn from this circumstance. In the first place, it should teach us charity to our neighbors, as it would explain the reason why a râle heard by one auscultator often could not be detected by another. In the second place, we might learn from it that a single examination was not sufficient to furnish a clear diagnosis.

Dr. E. V. Agramonte said that he regretted that Dr. Roosevelt had not said more about the subject of prognosis, since there were a considerable number of cases of phthisis which seemed to recover.

Dr. Roosevelt said that he had been obliged to omit a portion of his paper relating to the matter of prognosis. While the statement made by Dr. Flint some years ago, that about fifty per cent. of all cases of phthisis recover, was no doubt strictly true, he thought it had been the production of considerable harm by encouraging physicians to take a more favorable view of phthisis in general than they ought. The statement was based on the fact that so many cases of cured tuberculosis were found in the dead-house; but it was to be remembered that such an estimate would by no means apply to the consumptive patients who came to us for treatment.

Demonstration of a New Method of Obtaining Small Quantities of Stomach Contents for Diagnostic Purposes.—Dr. Max Einhorn read a paper on this subject (see p. 63).

Pilocarpin is recommended by Dr. Hochzeit in chronic rheumatism.

ONTARIO MEDICAL ASSOCIATION.

Tenth Annual Meeting, held at Toronto, Wednesday and Thursday, June 11 and 12, 1890.

(Reported by Our Canadian Correspondent).

J. A. TEMPLE, M.D., PRESIDENT, IN THE CHAIR.

THE Tenth Annual Meeting of the Ontario Medical Association, was held in the Medical Council Hall, Toronto. There was a large attendance of medical men from every part of the Province, with several visitors from the United States, including Dr. T. A. Emmett and Dr. Andrew Smith, of New York, and others.

Diagnosis and Local Treatment of Tubercle, or So-called Phthisis of the Larynx.—After the transaction of preliminary business, DR. C. TROW, of Toronto, presented a paper on the above subject.

After carefully enumerating the various methods of local treatment a number of interesting cases were reported illustrating the importance of persistence in treatment with favorable prospects of success.

DR. JENNER, of Kingsville, read notes of two cases, "Morton's Method in Spina Bifida," and "Poisoning by Antifibrine." These subjects were discussed by Dr. Groves, of Fergus, Dr. Freeman, of Buffalo, and Dr. Butt, of Paris.

The President's Address.—DR. J. A. TEMPLE, after thanking the Association for the honor conferred upon him, paid fitting tribute to several active members of the Association who had died during the year. Regarding the resolution that was passed last year to memorialize the Dominion Government that all surgical instruments should be admitted free of duty, he explained what action had been taken, but regretted to have to report that their efforts to secure this much-desired reform had so far been fruitless.

Medical Registration.—No change had taken place during the past year in reference to medical registration, between the medical authorities of this Province and those of Great Britain. This, he considered, was to be regretted, for he held that in no country, not even in England, was a higher standard of medical education required of students than in the Province of Ontario. He hoped the time would come when they would have reciprocity in medical practitioners. The Medical Council of Ontario was quite willing to register English practitioners in this country, providing that a similar privilege of registration in England was accorded to Canadians. It was a matter of regret that an agreement of this kind had so far not been arrived at. The English authorities, while fully recognizing the high standard of our examinations, were not willing to place those who had passed our licensing board in the English register. They offered to place them on a colonial register, an offer which was justly declined, for acceptance of such would place our graduates on the plane of inferiority. While we could not well agree to reciprocity on other than an equal footing, yet he hoped that a way out of the present difficulty might be found. The fact that for every Canadian who desired to register and practise in England there would probably be five or more English practitioners who would desire to register and practise in Canada made it evident that the English graduates had more to gain through a satisfactory settlement of the question than had their Canadian fellows to lose.

Uniform Medical License.—He entered a strong plea in favor of securing a uniform medical license for the whole Dominion, as it bordered on the ridiculous that a man, who had passed the prescribed examinations of the Ontario Medical Council should be obliged to pass examinations before the Medical Councils of the other provinces of the Dominion if he wished to practise in another province. The habit of medical men attending lodges and clubs for an annual fee he deprecated as being an injury to the profession, and regretted that the custom was becoming more widespread every day. These methods lowered the standard of the profession in the eyes of the public. Those who indulged in these practices did themselves a great injustice, for a uniform standard of fees should be maintained.

Dr. Temple then referred to the history of the Association, and noted with admiration its great progress and the interest shown in its meetings by the large attendance and the amount of scientific work done at each gathering.

He said: "The character and honor of the profession is in our own hands, individually as well as collectively, and just in proportion as we strive to raise it in public estimation will be the measure of our success."

The Standard of Education required of medical candidates had made rapid progress during the past two decades, and the president hoped to see the day when all medical and law students would be obliged to take a university degree before entering on their purely professional studies. One reason why more medical men did not contribute to the medical press was that they found themselves weak in the ground-work, a fact that clearly demonstrated the importance of insisting that every student before entering the study of medicine should have a liberal education. Great progress had been made in clinical education, and thanks to the beneficence of some wealthy persons students now had in the Province of Ontario superior opportunities in the wards of our hospitals. Another good work performed by this Association had been to impress members of the profession that their duty was not only to cure, but also to prevent disease.

The promotion of public health was carefully considered and the appointment of medical health officers in every municipality in the province had been followed with pleasing and satisfactory results.

Actions for Malpractice.—Dr. Temple expressed the hope that the session would not close without appointing a committee to memorialize Parliament to have the law so amended, if possible, that in all suits for malpractice security for costs to the defendant shall be given. It was, he said, a scandalous thing that in such suits they should be obliged to pay not only their own costs but the costs of the other side. To render keener the injustice it was notorious that in many instances where these actions were brought the services of the physician had been given gratuitously because the patient was too poor to pay for them.

Etiology of Puerperal Fever.—He closed his address by referring to the etiology of the so-called puerperal fever and the best method of preventing rather than of curing this dread complaint. After alluding to the various causes and conditions that might give rise to the disease he urged the importance of attending carefully to all the preparations and details at the time of delivery. The surroundings of the patient and the thoroughly aseptic character of everything brought in contact with her must be carefully considered.

After reviewing the different methods of treatment of the disease Dr. Temple concluded his interesting address as follows:

"I wish to express my thanks to those members of the various committees who have kindly aided me in the discharge of my duties, and I particularly wish to thank our efficient secretary for his uniformly kind attention and prompt and efficient discharge of his duties."

A hearty vote of thanks was tendered to the president for his able and interesting address.

DR. T. A. EMMETT, of New York, received a hearty greeting on being introduced to the Association. He read an instructive paper on "Lacerations of the Cervix Uteri and the Indications for its Restoration."

In an interesting address Dr. Emmett gave a history of the operation which bears his name. After carefully describing the conditions calling for treatment, and referring to those cases for which no operation is required, he entered into an extended review, clearly outlining the various steps and considering the most improved methods of the operation. An interesting discussion followed.

The Association then divided into sections.

Medical Section.—Dr. Chas. Sheard, of Toronto, was elected chairman and the following papers were read: "Duodenal Ulcer," by Dr. J. H. Duncan, of Chatham, Ont.; "Arthritic Hæmoptysis," by A. McPhedran, of Toronto; "The Vomiting of Pregnancy and its Treatment," by Dr. W. Irving, of Kirkton; "Paroxysmal Hæmaturia," by Dr. H. J. Saunders, of Kingston.

Surgical Section.—Dr. W. Burt, of Paris, was elected chairman and the following papers were read and freely discussed: "Traumatic Tetanus and its Treatment," by Dr. T. R. Dupuis, of Kingston; "Remarks on the Management of Talipes," by Dr. B. E. Mackenzie, of Toronto; "A case of Convergent Strabismus with Crossed Diplopia," by Dr. A. B. Osbourne, of Hamilton; "Scrotal Tumors," by Dr. A. B. Welford, of Woodstock.

Hernia.—At the evening meeting, Hon. Dr. Sullivan, of Kingston, opened the discussion in surgery by reading a paper on "Hernia," reciting in detail the latest methods for its radical cure. The discussion of the subject was continued by Dr. Grassett, of Toronto, and Dr. Waugh, of London.

This was followed by an instructive paper by Dr. Andrew Smith, of New York, on "Empyæma, with the Mechanical Results of Opening the Thorax." He illustrated his remarks with the appliances recommended by him in the treatment of such cases.

Dr. G. M Aylesworth, of Collingwood, opened the discussion in medicine, having for his subject, "A Plea for a More Liberal and Scientific Investigation on the Part of the Regular or Rational School of Medicine." This was an interesting paper and provoked an instructive discussion with which the first day's proceedings closed.

The Association first assembled in sections on the second day.

Surgical Section.—Dr. Groves, of Fergus, read a paper on "Perityphlitic and Pelvic Abscesses," and Dr. J. F. W. Ross, of Toronto, another on "Some Cases of Extra and Intra-peritoneal Inflammation—a Plea for the Operative Treatment of Peritonitis." The two subjects, being intimately related to each other, were discussed together. Dr. Grove's remarks were of a general character, dealing with inflammatory attacks in their widest sense and concluded by a review of the treatment, instancing the importance of early operation as soon as the symptoms called for surgical interference. Dr. Ross dwelt on the fact that many cases of loss of life resulted from the reluctance of many medical men to operate at the proper time. Too many adhere to the medical treatment of the patient in peritonitis and when too late agree to an operation. He strongly recommended that in all such cases, which were now quite common on account of persons taking part in sudden, violent exercise, the seat of the trouble should be reached and relieved by the surgeon, through whose skill much might be done to lessen the high mortality in peritonitis.

The president, Dr. Temple, and several others took part in the interesting discussion which followed.

Dr. C. M. Smith, of Orangeville, presented a paper on "Ruptured Peroneum," and Dr. J. Wishart, of London, read a paper on "Abdominal Nephrectomy for Hydronephrosis," and submitted an interesting report of two operations. Dr. H. Howett, of Guelph, submitted a report of a case of "Acute Suppuration of the Knee-joint with Complete Restoration of Function." Dr. A. B. Atherton, of Toronto, read notes of a case of "Hysterectomy for Fibro-cystic Tumor," and exhibited the patient and the tumor to the section. Dr. F. W. Strange, of Toronto, continued the discussion.

Medical Section.—Dr. J. L. Addison, of St. George, presented a paper on "The Treatment of Pneumonia." He mentioned that during the past year this disease had been more prevalent and fatal in Canada than usual. Primary pneumonia, although admitted to be a self-limiting disease, should have judicious treatment. The first essential in treatment was rest in bed in a well-ventilated room, and absolute freedom from all worry and excitement. Good nutritious food in a fluid or semi-fluid state should be freely given. The chest should be protected with a layer of cotton batting. After enumerating the remedies commonly employed in the treatment of an ordinary case of pneumonia he made reference to the several complications which might arise, such as pleurisy, hyperpyrexia, delirium, coma, jaundice, diarrhœa, malaria, and abscess of the lung, and the treatment suitable for each. Secondary pneumonia was most frequently met with in, or as a complication of, influenza, measles, whooping-cough, or typhoid fever, and might require more energetic treatment. His experience had taught him to prefer the expectant plan of treatment, sustaining the vital powers, watching complications, and treating them as they arise, making every case a special study. Opium, if used at all, must be used with caution. Digitalis in moderate doses as a heart tonic with free stimulation for heart failure had been very satisfactory in his cases. An excellent discussion followed the reading of this paper.

Dr. A. Jukes Johnston, of Toronto, presented a paper on "Some Recent Treatments Recommended in Diabetes." Dr. J. L. Bray, of Chatham, read a paper on "Typhoid Fever." Dr. W. H. Moorehouse, of London, contributed a paper on, "Influenza, its Complications and Sequelæ," and gave an interesting sketch of some of the phenomena connected with the recent epidemic. Instructive discussions followed the reading of each paper.

Dr. G. S. Ryerson submitted a paper on "The Ophthalmoscope in Relation to Diseases of the Nervous System." He emphasized the correspondence between the development and functions of the brain and those of the optic nerves, since these last were genetically direct and early outgrowths of the brain. It was also notable that the eye and its appendages received the whole or parts of six out of the twelve pairs of cranial nerves. These things pointed to the intimate relation that existed between the eye and the rest of the body. No other organ of the body contained so many different kinds of histological elements or textures of so high a quality as the eye, and hence the immediate participation of the eye in general and constitutional diseases. Hence the importance of examining the eye ophthalmoscopically in cases of brain diseases and suspected organic disease of the nervous system. He briefly passed in review a few of the diseases of the brain in which the ophthalmoscope might be of especial use in diagnosis. In such diseases as neuritis, where the vision was good and there were no external signs of danger, the ophthalmoscope alone would reveal the pathological condition, and it was of immense advantage in cases of insanity and atrophy. Having drawn attention to the intimate relationship between diseases of the brain and disease of the optic nerves, he proceeded to show the connection between diseases of the cord and those of the optic nerve. He drew the following conclusions from the facts he had stated in his interesting paper:

1. That diseases of the brain and spinal cord are frequently associated with ocular disturbances.

2. That serious eye trouble may be present without subjective symptoms.

3. That eye troubles often precede and give a warning of impending nerve disease.

4. That diseases of the optic nerve and retina are of great diagnostic value in nervous diseases.

5. That it is the duty of the physician to examine the eye and its muscles in all cases of nervous disease.

In the discussion which followed, Dr. Palmer and Dr. Wishart, of Toronto, earnestly advocated the study and use of the ophthalmoscope, especially since nervous diseases were becoming more and more common.

Obstetrics.—The discussion on obstetrics was opened by Dr. A. T. Carson, of Toronto, who read an interesting paper on, "The Prevention of Post-partum Hemorrhage." He said he had nothing new to offer on the subject, but dwelt with emphasis on its importance and gave

the results of his personal observation in the course of a lengthened period of practice.

Expectorants.—At the evening session the discussion on "Therapeutics," was opened by DR. J. L. DAVISON, of Toronto, who had for his subject "Expectorants." After reviewing the history of this class of remedies he unhesitatingly condemned many of the so-called cough mixtures prescribed at the present day. He freely condemned the too frequent use of opium in respiratory troubles for the purpose of "breaking up a cough."

DR. SPENCER, of Toronto, who continued the discussion, spoke of the value of preparations of tar as expectorants.

DR. T. H. GREER, of Cold Springs, presented the Report of the Committee on Public Health. Among the practical suggestions made was the necessity of determining what length of time must elapse before a diphtheria patient should be allowed to mix with the general public. Some changes were suggested in the regulations for quarantine, and the charges made last session in the Public Health Act were noted with satisfaction. The proposed establishment of a hygienic laboratory was brought before the Association in the report, but no action was taken pending a fuller discussion of the proposition. The report was ordered to be conveyed to the Chairman of the Provincial Board of Health.

The Committee on Legislation presented a report which was read by DR. G. M. AYLESWORTH, of Collingwood, and their findings were referred to the Medical Council. A discussion took place on the bad wording, as the members understood it, of the law that allowed quacks and druggists to prescribe on condition that no questions were asked as to the patient's ailments. It seems that, according to the interpretation of the law by the courts, interrogating patients, not in prescribing for them, constitutes infraction of the Ontario Medical Act. The absurdity of this is at once apparent and early application will be made for a change in the reading of this part of the Act.

The Committee on Ethics reported, through DR. BURNHAM, of Toronto, and among other things condemned the practice, not altogether yet obsolete, of medical men receiving a percentage on the amount of prescriptions sent by them to druggists. All advertising was condemned alike for specialists as well as ordinary practitioners, and a few strong words uttered against giving the slightest encouragement to those who endeavored to persuade the medical man to prostitute his noble calling by attempting malpractice in any form.

The report of the Nominating Committee was presented and recommended the following

Election of Officers.—*President*, Dr. W. H. Moorehouse, of London; *First Vice-President*, Dr. Charles Sheard, of Toronto; *Second Vice-President*, Dr. J. W. Gibson, of Belleville; *Third Vice-President*, Dr. Powell, of Ottawa; *Fourth Vice-President*, Dr. J. Wishart, of London; *General Secretary*, Dr. D. J. Gibb Wishart, of Toronto; *Assistant Secretary*, Dr. W. P. Cavan, of Toronto; *Treasurer*, Dr. E. J. Barrick, of Toronto; *Committees—On Credentials*, Drs. Sheard, of Hamilton, and Lowry, of Acton; *Public Health*, Drs. N. J. Charlton, Weston, and Farley, of Belleville; *Legislation*, Hon. Dr. Sullivan, of Kingston, and Dr. Waugh, of London; *Publication*, Dr. J. L. Davison, of Toronto, and Dr. A. Primrose, of Toronto; *By-Laws*, Drs. Griffin, Hamilton, and Carson, of Toronto; *Ethics*, Dr. A. R. Harvie, of Orillia, and Dr. J. F. W. Ross, of Toronto.

Place of meeting 1891, Toronto.

Honorary Members.—The names of the following gentlemen were added to the list of honorary members of the Association: Dr. Joseph Workman, of Toronto; Dr. T. Addis Emmett, of New York; Dr. E. M. Moore, of Rochester; Dr. William J. Mickle, of Grove Hall Asylum, London, Eng.

Dr. Charles Sheard, of Toronto, paid an eloquent tribute to the memories of the members who have died since last meeting.

The treasurer's report was presented and was highly satisfactory.

After passing several resolutions of thanks in acknowledgment of courtesies received by the Association the president-elect was conducted to the chair and the proceedings of the tenth annual meeting were brought to a close.

Correspondence.

OUR PARIS LETTER.

SPRAINS OF THE ANKLE—SUBLUXATIONS OF THE FOOT—INHERITANCE OF SYPHILITIC TREATMENT.

PARIS, June 27, 1890.

DR. RECLUS, hospital surgeon, has published a note on the manner of his proceeding, in a general way, in the treatment of sprains or subluxations of the foot. This treatment is a mixed method, founded on the employment, successively, of an elastic bandage, hot foot-baths, and massage. As soon as the sprain is produced, the region affected should be enveloped with an elastic roller, the application of which should be commenced at the roots of the toes, and it should be rolled round the foot, on to the instep and about midway up the leg; it should be tightened just sufficiently for the roller to be kept in place. When the sprain is not very severe, slight movements may be permitted. Twice a day, morning and evening, the elastic bandage should be removed to wipe and dry the parts, as under the impermeable tissue there accumulates sweat which soon decomposes, assumes an insupportable odor, and, what is more serious, irritates the integuments. Without this precaution it might provoke eczematous, and even furuncular, eruptions. It is then that the second precept of the treatment should intervene. The affected joint should be plunged into a bath the temperature of which should be progressively raised until it attains 48°, 50°, and even 55° centigrade. Under its influence the pain ceases, if the elastic bandage had not already dissipated it, the circulation is increased, and perhaps also the nutritive changes. These divers modifications have probably a great deal to do in the more rapid resorption of the peri-articular exudations. It is also to promote resorption that massage is added to the pressure of the elastic roller, and this massage constitutes the third part of this mixed treatment. The elastic roller has certainly on massage the advantage of acting in a continued manner, but it cannot, like massage, expel from the meshes which contain them the solidified clots, for which purpose the strong pressure of the finger, "petrissage," would not be too much; it much better disseminates the peri-articular infiltrations and thus prepares for the elastic bandage. After the immersion of the foot in hot water for ten or fifteen minutes, after a *séance* of massage from ten to fifteen minutes, the limb is enveloped for twelve hours in the India-rubber bandage. The author observes that the sprain must be very severe if complete cure is not obtained in less than fifteen days.

A propos of this subject, I may here reproduce a note published in the *Semaine Médicale*, by Dr. Treuthardt, of Cossonay, on a new treatment of subluxations of the foot and of fracture of the fibula, which he has practised for the last twelve months. It consists in the applications on the part affected of a paste composed of glazed clay mixed with vinegar. The consistence of this mortar should be sufficient to enable one to envelop the affected limb, and that the apparatus be kept on as well as a plaster bandage. The application is made directly on the skin, and the dressing should remain in place from twelve to eighteen hours, until the almost complete desiccation of the glazed clay is complete, when it should be renewed. The author observes that this procedure rapidly produces the disappearance, and without pain, of the effusion, however considerable. In recent subluxations and fractures of the fibula one application of the glazed clay

suffices to cause the entire disappearance of the tumefaction of the articulation in from twelve to eighteen hours. If the accident dates from several days, or the tumefaction be very considerable, two or three apparatuses applied at intervals of twelve hours will remove it. The joint is not immobilized in the apparatus, the tumefaction disappearing very quickly, and the tissues not remaining infiltrated adhesions are not organized as in immovable apparatus. After the disappearance of the tumefaction Dr. Trenthardt applies an elastic and compressive dressing, by means of cotton-wool and a flannel bandage, and recommends the patient to execute frequently, in the wounded joint, all the movements which the dressing permits. At the end of from three to five days the patient should be able to walk, and the dressing should be sufficiently reduced to permit the patient to wear a laced shoe. In cases of fractures of the fibula treated in this manner all limping disappeared in fifteen days.

At the last meeting of the Société de Dermatology et Syphilographie, Dr. Fournier read a note for Dr. Cathelineau on the presence of mercury in the viscera of a fœtus born from a syphilitic mother submitted to mercurial treatment. Dr. Fournier observed that till now the presence of mercury in the urine of new-born infants whose mothers were treated with that drug had not been discovered. The researches of Dr. Porak, relative to this point, gave only negative results. In the case under notice mercury existed in the viscera of the fœtus, as proved by the researches of Dr. Cathelineau, and in different proportions according to the organs. The following are the proportions: Liver, 0.00121 gr. for 10 grammes of matter; spleen, 0.00120 gr.; heart, 0.00106 gr.; kidneys, 0.00106 gr.; meconium, 0.00046 gr.; lungs, 0.00034 gr.; brain, 0.00031 gr.

At the last meeting of the Association d'Avancement des Sciences, Dr. Galliard brought to notice a case showing that rachitism should not be attributed to syphilis, according to the theory of Parrot. A child submitted to bad hygienic conditions became rachitic. The parents, however, were not syphilitic at the time of the child's birth, but both contracted syphilis later on. Moreover, a second child was born when the parents were in the height of syphilis; but this child, being better nourished, did not present any trace of rachitism whatever. Another child, born in the interval before the syphilis, was not rachitic. Thus there were in this family a rickety child without syphilis, a child free from the two affections, and one child syphilitic without rickets.

Dr. Abadie believes that true sympathetic ophthalmia is a microbian malady of infectious origin. This new pathogenic conception permits us to explain many peculiarities of this terrible affection which were formerly incomprehensible. Dr. Abadie explains that the eye affected by traumatism constitutes a pathogenic focus whence come the microbes, which, by the intermediary of the chiasma, invade the opposite eye. If, then, enucleation be practised before the microbes invade the optic nerve, it is efficacious and preserves the eye. If, on the contrary, one waits till the sympathetic ophthalmia is declared, enucleation alone cannot always arrest the microbian evolution in the healthy eye. Whence hesitation in intervention, some being partisans, while others are adversaries of enucleation. Instead of practising ablation of the wounded eye, Dr. Abadie advises, when sympathetic ophthalmia is declared, to cauterize with a fine galvano-cautery the wound to its full extent, turning it in all directions so as to destroy the pathogenic focus. Moreover, he injects into the wounded eye one drop of a solution of corrosive sublimate of 1 per 1,000.

The Money Loss from Influenza.—It is estimated that the loss of wages due to the influenza in London amounted to five million dollars, and a like amount was paid out in insurance and sick-dues by the different mutual aid societies.

THE RECEPTION AND TREATMENT OF THE ACUTELY INSANE IN GENERAL HOSPITALS.

To the Editor of the Medical Record

Sir: In your issue of June 28, 1890, is an article upon the above subject by Dr. W. P. Spratling, of the Morris Plains Asylum, which, although written from the standpoint of the asylum physician, who might be expected to be somewhat opposed to an apparent innovation of this character, is still marked by a commendable liberality in its dealing with the question. There are, however, some points concerning which the author has misconceptions. An instance occurs in a sentence of which the following is one clause: "So radical a change, affecting as it most assuredly would do, the character of all general hospitals into which insane cases might be admitted."

Now, it is not precisely clear to me why the character of a general hospital should be changed by the admission of patients suffering from functional disorders of the brain, some of which we call insanity. Cases with other and somewhat similar brain affections are not refused admission, like the delirium of fevers or delirium tremens. Yet the character of the hospital is not materially altered. Indeed, the question of the propriety of admitting insane persons to general hospitals does not remain to be solved by the experiment of the hospital at Victoria, for it has already been solved by the successful experience of many general hospitals during many past years.

The Vienna General Hospital has had, for a longer time than I can remember, a number of wards for the insane. Professor Meynert and his assistants are the visiting physicians in this department.

The Charité, of Berlin, has wards set apart for the insane.

The Bremen City Hospital counts among its buildings two large pavilions for the accommodation of some one hundred and fifty insane patients.

In Paris the Salpêtrière and Bicêtre, each provide wards for this class of unfortunates.

I do not, at this moment, recall the other foreign institutions similarly constituted, but it is not necessary to go so far from home to see a general hospital with proper facilities for the reception of the insane.

The Bellevue Hospital has a roomy pavilion on its limited grounds for these cases, and its construction was a great boon to New York City.

Would the doctor intimate that the character of any of these general hospitals just mentioned has been radically changed by these provisions? If so, is the change for the better or for the worse?

In the same sentence the author implies that it would be "robbing existing asylums or hospitals for the insane of the very cases the State intended these institutions should receive." This is another misconception on his part. The paragraph from the report of a committee of the New York Neurological Society which prompted the writing of his paper reads as follows:

"5. A clause should be introduced into the bill providing that nothing in the lunacy laws of the State shall be construed to interfere with the reception and treatment of acute cases of insanity in chartered general hospitals, in the same manner and under the same conditions as patients suffering from other diseases are there received and treated, provided such hospitals have suitable accommodations approved by the State Commission in Lunacy."

Such a law, if passed, instead of forcing all of the acutely insane to be sent to general hospitals would merely permit these institutions to receive the insane, if, like Bellevue or the Marshall Infirmary of Troy, they are provided with suitable accommodations. I do not see how anyone can gainsay the beneficence of such a provision, particularly in towns and cities remote from the hospitals for the insane established by the State.

Buffalo, might perhaps dispense with general hospital accommodations for the insane, for patients can be re

moved with but little delay to a model State asylum in her very midst. This is also true of Utica and Ogdensburg and Poughkeepsie and Middletown. But what is to be done in emergency with the acutely insane of Syracuse, Rochester, Albany, and Plattsburg? Troy has partially solved the problem on her own account. When patients in Troy are not in proper condition for the journey to Utica or Poughkeepsie, or when their friends prefer a general hospital, they are placed in her Marshall Infirmary, which is another example of a general hospital with a large insane department. As regards New York City, the pauper insane may be despatched at once to the pavilion at Bellevue, by ambulance if necessary; and although under existing laws there is no legal right to receive them there without certain papers, it is done, and no one will complain, because it is so much better that they should go to a general hospital, pending the making of certificates, than to a jail or station-house. They are examined and treated while there, and often discharged as not proper cases for commitment to the asylum. The rich may be treated at their own homes for an indefinite period if it is so desired, or until they can be transferred to some private hospital for the insane, because isolated apartments, a sufficiency of nurses, and, in fact, everything requisite is at their command. But the real sufferers in New York are the middle classes, since the insane of this class cannot be sent to Bellevue, and cannot remain long at home. Bloomingdale is overcrowded, and is soon to be removed to the country. What a blessing it would be if Roosevelt Hospital should cause an insane pavilion to be constructed upon a part of its vacant area, and it some of the other metropolitan general hospitals would do likewise!

A psychopathic hospital, such as it is contemplated to build in London, is perhaps a greater desideratum for the large university cities than wards in general hospitals, not only for the purpose of securing the best treatment and the deepest scientific study of the insane, but also for the more thorough instruction of medical students in morbid psychology. But like that of receiving and treating the insane in general hospitals, the conception of a psycopathic hospital is neither novel nor unique, for the Psychiatrische Klinik of Leipzig, under the supervision of Professor Flechsig, and that at Strassburg, in charge of Professor Jolly, are psycopathic hospitals of a number of years' standing, embodying all that is best in Germany with regard to plan of construction, internal management, treatment of patients, the physiological and pathological study of the central nervous system, and the instruction of students in psychological medicine.

FREDERICK PETERSON.

201 WEST FIFTY-FOURTH STREET.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 7 to July 12, 1890.

BALL, ROBERT R., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Riley, Kan., and will report in person to the commanding officer at Fort Spokane, Wash., for duty. Par. 7, S. O. 151, A. G. O., Washington, D. C., June 28, 1890.

KIMBALL, JAMES P., Major and Surgeon. By direction of the Acting Secretary of War, leave of absence for four months is granted, to take effect when an officer of the Medical Department is assigned by his department commander to relieve him. Par. 6, S. O. 152, A. G. O., Washington, D. C., July 1, 1890.

TAYLOR, MARCUS E, Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted on surgeon's certificate, in S. O 45, June 13, 1890, Division of the Pacific, is extended five months on surgeon's certificate of disability, with permission to go beyond sea. Par. 6, S. O. 159, A. G. O., July 10, 1890.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. Having been found incapacitated for active service by an army retiring board, and having complied with par. 12, S. O. 135, June 10, 1890, from this office, is, by direction of the Secretary of War, granted leave of absence until further orders, on account of disability. Par. 3, S. O. 153, A. G. O., Washington, D. C., July 2, 1890.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon. Relieved from temporary duty at the United States Military Academy, West Point, N. Y., to take effect upon the arrival there of Captain W. Fitzhugh Carter, Assistant Surgeon, and will then report in person to the commanding officer of Fort Du Chesne, Utah Ter., for duty, relieving Captain Curtis E. Price, Assistant Surgeon. Par. 12, S. O. 153, A. G. O., Washington, D. C., July 2, 1890.

PRICE, CURTIS E., Captain and Assistant Surgeon, on being relieved by Captain Robinson, will proceed to Fort Wadsworth, New York Harbor, and report in person to the commanding officer of that post for duty, relieving Captain Robert B. Benham, Assistant Surgeon. Par. 12, S. O. 153, A. G. O., Washington, D. C., July 2, 1890.

BENHAM, ROBERT B., Captain and Assistant Surgeon, on being relieved from temporary duty at Fort Wadsworth, to report in person, without delay, to the commanding officer at Fort Hamilton, New York Harbor, for duty. Par. 12, S. O. 153, A. G. O., Washington, D. C., July 2, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 12, 1890.

PAGE, J. E., Assistant Surgeon. Ordered to hospital, Mare Island, Cal.

KENNEDY, R. M., Assistant Surgeon. Ordered to the League Island Navy Yard, Pa.

RIXEY, P. H., Surgeon. Granted leave of absence for fifteen days.

OGDEN, F. N., Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

WHITE, S. STUART, Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

ATLEE, L. W., Assistant Surgeon. Granted three months leave of absence.

WOOLVERTON, T., Medical Inspector. Ordered to the Philadelphia.

LOVERING, P. A., Passed Assistant Surgeon. Ordered to the Philadelphia.

MCMURTRIE, D., Medical Inspector. Granted leave of absence for thirty days.

Where Travelling is not Altogether Pleasant.—Travellers on the Eastern Bengal Railway have placed before their eyes on entering the stations of the road, a placard containing the following cheerful information: "Passengers are hereby cautioned against taking anything to eat or drink from unknown persons, as there are many who live by poisoning travellers. They first of all court acquaintance with passengers in a *sarai* or some other place, and then gain their confidence on the plea of being fellow-travellers going to the same place. When they reach a place convenient for the purpose, they poison the water or food of the passengers, who become insensible, and then they decamp with all their property. They also at times poison the passengers' water when being drawn out of wells, or sweetmeats brought from the bazaar, or food when being cooked."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 12, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	19	0
Scarlet fever	30	5
Cerebro-spinal meningitis	0	4
Measles	327	25
Diphtheria	91	21
Small-pox	0	0
Varicella	5	0
Pertussis	3	14

Surgeon Parke.—The Cairo correspondent of the *Lancet* gives some interesting particulars concerning Surgeon T. H. Parke, who accompanied Stanley. He has been in the British service nine years. He was in Egypt during the Tel-el-Kebir campaign of 1882, and the next year served through the cholera epidemic in Cairo, and was in charge of the cholera camp at Helonar, where 250 out of 550 English soldiers were down with the disease, and there was a great mortality among the medical staff corps in consequence of their constant attendance on the sick. His report on this camp was published in the Blue Books, and he was specially thanked for his services by Surgeon-General Irvine. During the Nile campaign of 1884–85 he was well to the front, and by his hard work earned the friendship of all with whom he came in contact. He marched with Sir Herbert Stewart's column across the desert, and was present at the actions of Abu Klea, Gubat, and Metemmeh. He was at first in medical charge of the Naval Brigade under Lord Charles Beresford, when every man except himself was killed or wounded, and then returned to Korti upon the retreat in charge of the Guards' Camel Corps, with whom he remained at Dongola till the close of the campaign. For this he received the medal with clasps for the Nile and Abu Klea, and also the Khedive's bronze star. In February, 1887, Surgeon Parke accepted Stanley's invitation to join the expedition for the relief of Emin Pasha, signed a contract of agreement to go as a volunteer without remuneration of any kind, and obtained leave without pay from the military authorities. He left Egypt with Stanley on February 4th for Zanzibar, where seven hundred porters had to be engaged and vaccinated. This vaccination seems to have saved their lives in a wonderful way at a time when the non-vaccinated natives were dying of small-pox at a rate which threatened to seriously hamper the expedition. From Zanzibar he went straight to the mouth of the Congo, and then with a flotilla of Congo steamers to Yambuyo, one thousand miles from the coast. He then accompanied Stanley and the advance column in all their weary wanderings, and through the hardships of which we do not yet know a tenth part. When Stanley got safely to the coast he wrote in his official report: "If the expedition has been happy in anything, it is in the selection of its unrivalled physician and surgeon, Mr. Parke." Moreover, Stanley and some of the other officers of the expedition have freely admitted to the writer that they owe their lives to him, and in private they can never praise him too highly. Stanley, from his own account, seems to have been ill for six weeks in the forest, which had an area of two hundred and fifty thousand square miles. He suffered from subacute gastritis at a time when nearly half the men died of starvation. There were practically no food and no sunshine, and a long convalescence, during which life had to be sustained with forest fruits, green tops of bushes, roots, bananas, and fungoid growths clinging to decaying trees. For a long time he had to be fed with an india-rubber tube, and was too weak to turn himself in bed. Then, again, a year later he was laid low by a similar attack, followed by a much longer convalescence, during all which time he required careful nursing. It is easy to guess what would have become of the Relief Expedition if Stanley's valuable life had not been saved. One of the most memorable incidents of Mr. Parke's services during the three years' wanderings was when Mr. Stairs was wounded by a poisoned arrow near the apex of his heart. The latter believes that he owes his life to Mr. Parke, who sucked all the poison from the wound at the risk of his own life. Many men wounded by similar arrows on the same day died of the effects of the poison within a couple of days. Some samples of these wooden arrows with the poison and its antidote have been sent home for future analysis. When the explorers at last reached the coast, and were just preparing for their well-earned repose, poor Emin Pasha, as all the world knows, fell out of a window thirty feet high, and fractured the base of his skull. Directly he recovered consciousness he asked for Mr. Parke and begged him to stay with him, the German medical men disagreeing with their English colleague's less gloomy prognosis. While engaged in day and night watching at Bagamoyo, Mr. Parke was laid prostrate by bilious intermittent fever, with copious hæmaturia. He was carried on board a steamer, collapsed and believed to be dying. He arrived at Cairo on January 16th, convalescing from fever, hardly able to walk upstairs, thin, weak, anæmic, with great staring eyes; but a few days later he began his ordinary medical duty at the Citadel Hospital, and since then his weight has gone up to 173 lb. from 132 lb., which was his lowest record in Africa; and this is only a sign of the general improvement in his health. The Khedive has already recognized his services by giving him the third class of the Medjidieh, and the Royal College of Surgeons of Ireland has shown a prompt appreciation of his work worthy of being imitated, by making him an honorary Fellow, a distinction possessed only by six other living people. In the ordinary course of events, he must become a Surgeon-Major in about two years' time, but it is hoped that this time will be shortened by reason of the hazardous services upon which he has been engaged.

The Etiology of Rickets.—Hecquet maintains that rickets is never found in breast-fed children, but only in those fed artificially, and that therefore the disease depends on faulty combination of the food elements. He had noticed that beasts in the Zoological Gardens very often are affected with a disease of the bone-tissue, which is ascribed to the confinement. This "Zoological Garden disease" is certainly rickets, and affects the young, not fully-grown, beasts, whether born in confinement or not. The treatment, which consisted in the addition of bone-meal food, was unsuccessful until a fat-containing food was added. The result was then very satisfactory. Starting from this experience, Hecquet commenced his researches on the rachitic disposition, and now feels justified in asserting that the appearance of rachitic symptoms stands in close relationship with scrofula, and that every artificially-fed child who acquires rickets is really already scrofulous. He regards the stomach and bowel affection, giving rise to diarrhœa ablactatorum, on the first sign of rachitic digestive anomaly, depending on the presence of too little fat in the food. The truth of his observations, he thinks, is confirmed by the good effect of his treatment of diarrhœa ablactatorum and rachitis with a fat-containing food. He gives boiled milk and oatmeal gruel in equal parts, with one to three tablespoonfuls of cream, and one teaspoonful of milk-sugar. This is to be prepared fresh each time, and given every two hours. Instead of cream other fat can be employed, as butter, cod-liver oil, or cocoa-butter.—*Medical Recorder*, April 20, 1890.

Methacetin.—This is the name of a new synthetic remedy possessing antipyretic and analgesic properties. It occurs in the form of a faint rose-colored powder,

without taste or odor. Dr. Seidler reports some experiments in the *Berliner Klinische Wochenschrift*, No. 15, 1890, from which he concludes that the drug is an efficient antipyretic, the temperature beginning to fall within from fifteen to thirty minutes after the remedy has been taken by the mouth. He did not observe any depressing effects upon the heart. The dose is from four to six grains.

Poisoning from Antipyrine.—It is stated that no less than seventeen fatal cases of poisoning from antipyrine occurred in one week in Vienna during the prevalence of the influenza. In many of these cases the drug was bought by the victims themselves without a physician's prescription, but, partly in consequence of these fatalities, it is now illegal to sell antipyrine except upon a written prescription from a physician.

The Use of Leeches in Bacteriology.—Dr. Pasternatski has found that a very convenient method for collecting and preserving for cultivation the spirillum of relapsing fever is to use leeches. If the leeches are kept in a cold place, the spirilla they contain preserve their vitality for a considerable period, much longer than they do when kept in capillary or other glass tubes. When exposed for some time to a temperature of from 27° C. to 30° C. the spirilla were found to undergo transformation into other forms.—*The Lancet.*

A Supplemental Nervous System.—Dr. H. W. Loeb, of St. Joseph, writing in the *Weekly Medical Review*, argues that there is no such thing as sympathy peculiar to the so called sympathetic nervous system which is not resident also in the cerebro-spinal system. He believes that the two systems are similar in nature, and that the sympathetic is but an outgrowth of the cerebro spinal. He proposes therefore to call the former the supplemental nervous system.

Female Druggists.—A daily journal has recently pointed out that pharmacy is now quite open to persons of the female sex, and suggests, what is certainly true, that it is a calling for which their neat touch and delicacy would seem peculiarly to suit them. For a long time there were difficulties in the way, but these have now been overcome, and there is no reason why lady chemists should not commence business, under the patronage—if they can secure it—of the lady doctors.—*Lancet.*

Why Not, if He is Honest?—A contemporary notes as a remarkable occurrence that Mr. Jonathan Hutchinson recently exhibited a case of skin disease before a medical society, with the statement that he was unable to make the diagnosis. We are not told whether the wonder is that the gentleman was unable to make a diagnosis, or that he was willing to acknowledge his ignorance.

Salicylate of Sodium in Pruritus.—Dr. Wertheimer reports the case of a woman suffering from universal cutaneous pruritus of nervous origin, for the relief of which he tried salicylate of sodium in fifteen-grain doses three times a day. After the third dose she enjoyed the first night's undisturbed sleep she had had for a long time, and by the fourth day all itching had entirely ceased. Smaller doses were given for a few days longer, and she has since remained free from any return of the pruritus.

Chemical Salts Developed in Living Organisms.—A memoir by Mr. Robert Irvine and Dr. Sims Woodhead, entitled "Secretion of Carbonate of Lime by Animals," recently published in the *Proceedings of the Royal Society of Edinburgh*, deals with the interesting question of the assimilation of food and the development of structures partially composed of a definite proportion of insoluble chemical salts. Thus, hens supplied with sulphate of lime, but no other lime salt, produce well formed egg-shells composed of carbonate of lime. The process of shell formation in the crab appears to differ chemically from egg-shell development in the hen. Sulphate of lime is not assimilated in the same manner, so that crabs which throw off their shells in artificial sea-water in which sulphate of lime as well as chloride of sodium are present, but from which chloride of calcium is excluded, do not form a new exo-skeleton of carbonate of lime. As soon as chloride of calcium is added, although the sulphate be withheld, shell formation may go on. The authors of the paper minutely describe the share which epithelial and other cells play in secreting, or causing the deposit of, chemical salts in shells, and in bone. The histological and chemical processes differ considerably in bone, in egg-shells, in the shells of crustacea, and in the "mantle" of mollusca.—*British Medical Journal.*

Medical Instruction in Kieff.—The Faculty of Medicine at Kieff was founded in 1840, but the University has been in existence since 1835. The total number of students in all the faculties of the University is 2,600, of whom 900 are students of medicine. The period of study extends to ten sessions, comprised in five years. The two first years are devoted to the theoretical and practical study of the natural sciences—anatomy, physiology, chemistry, inorganic, organic, and physiological; physics, zoology, botany, etc.; thirty-three hours a week are thus occupied. At the end of these courses an examination is passed, and the student turns to the study of the strictly medical subjects for three years. Another examination is held during the last half-year, and the successful candidate receives the diploma of "Doctor." In order to obtain the diploma of "Doctor of Medicine" another more difficult examination has to be passed, and a thesis must be submitted and sustained by public argument.—*British Medical Journal.*

Glaucoma in Early Life.—Dr. Laqueur, of Strasburg, has met with six cases of glaucoma in persons far above the age at which this disease is usually observed. Four of them were males, aged seventeen, twenty-three, twenty-five, and thirty-six years, and two were women of seventeen and twenty-four years, respectively. Such cases are not unknown, but the vast majority of sufferers are aged over forty-five or fifty. In one only had there been any irritative prodromata, the disease being simple in the remaining five. In all it was unilateral, but in one the other eye was affected later. They complained of cloudy vision, with colored rings. From these cases he concludes that glaucoma occurring in young adults differs from that seen in more advanced life, in the anterior chamber not being flattened, indeed rather the reverse, the iris being normal and the pupil sensitive to light or fairly so, and the globe not so hard and tense, though the "cup" was well marked in all.—*The Hospital.*

An Opening for Dentists.—An American missionary from India says that there is a chance in Madras and Bombay for a number of bright, skilled American dentists. Madras is a city of three hundred thousand population, and has not a single American dentist. People sometimes travel from there to Bombay, nearly one thousand miles, in order to have a tooth filled. There is only one good dentist in Bombay, and he refuses to fill teeth with gold, using a sort of cement that is not lasting. He charges seven dollars and fifty cents for pulling a tooth.

Suicide by Means of a Pin.—At a recent meeting of a Parisian medical society, Dr. Magnan related the case of a young woman suffering from melancholia, who was determined upon self-destruction, and to this end stuck a pin of ordinary size into her chest just below the left breast. The pin passed through the sixth intercostal space, into the pericardium, and lacerated the myocardium. Death supervened from syncope, the heart stopping from a quantity of blood filling the lower part of the pericardium, although no important vessel was wounded.

SPINAL SURGERY—A REPORT OF EIGHT CASES.[1]

BY ROBERT ABBÉ, M.D.,

SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK; PROFESSOR OF SURGERY POST-GRADUATE SCHOOL, ETC.

I HAVE the pleasure of presenting this evening, not a rose-tinted picture of startling achievements of new surgery, but rather a serious review of some of the grave cases of spinal troubles requiring surgical interference which have of late come under my care. They had all been subjected to prolonged medical treatment and were, when referred to me by the physicians or neurologists, in nearly a hopeless condition. Almost as many more cases have been refused operation, but these seemed either to offer hope of relief based on experience, or to give legitimate opportunity for novel operative methods based on sound physiological principle.

The popular idea among physicians has been that the spinal cord is more inaccessible to the surgeon than the brain, by reason of its irregular bony coverings and the hemorrhage from the venous plexuses that envelop it, and that injuries and diseases of it are to be looked upon hopelessly unless nature kindly assumes to work unexpected recoveries. This view is shared even by the public.

It is from the ranks of these doomed cases of paralysis of the lower half of the body and some other spinal troubles that an effort is being made to cull out some cases which, heretofore neglected, may yield good results.

A few noteworthy articles have appeared during the past two years reporting operative cases. Those by Horsley, MacEwen, Thorburn, White, Bullard and Burrell, Winslow, Dandridge, and Bennett are of special interest.

It is evident that some cases of improvement have been reported prematurely, and it is fair to ask some months' delay before a published report.

Especial interest has been aroused by the brochure of William Thorburn, of Manchester, just issued, giving, I believe, the most thorough and dispassionate review of this field that has yet been made. While realizing that his most lucid views are based on the study of all cases reported up to the present, one is struck by the fact that these are comparatively few. The need of reporting carefully all cases where operation is done leads me therefore to present the following eight cases which may be divided into four groups.

Three of paraplegia from fracture. One of early curetting of a vertebra for Pott's disease. Two of tumors of the vertebral canal with paraplegia. Two of intradural section of some of the posterior roots of the brachial plexus for neuralgia.

I will read the three fracture paraplegia cases together. The first one was:

CASE I.—*Fracture of the Spine between the Eleventh and Twelfth Dorsal Vertebræ, Complete Paraplegia and Anæsthesia with Incontinence; Operation, Eleven Months Afterward, Breaking up Intradural Adhesions; Suture of Dura; Primary Union; no Relief of Paralysis up to One Year afterward.*—R. M. G——, aged twenty-seven, merchant; a gentleman above the average height and in good health until May 19, 1888, when he fell from a platform twenty-one feet high, while pushing off a large beam. Fell with the timber on sawdust-covered ground, receiving scalp wounds, but it is impossible to say whether the timber struck him or not. He was unconscious for three hours, and was completely paralyzed and insensitive below his waist when he recovered. Efforts were made, under ether, to straighten the fracture deformity of the spine by extension and manipulation, but nothing was gained. A bed-sore formed over the deformity and a water bed was obtained. At first it was filled with very cold spring water, and he suffered such pain on being placed upon it that he fainted and was unconscious for hours. Complete incontinence of urine occurred from the first, and his bladder was irrigated for cystitis. Diarrhœa was succeeded later by complete inaction of the rectum, requiring the persistent use of laxatives.

After three months he resorted to a wheel-chair and attended to business. This was his condition in April, when he was brought from Texas to Dr. Lewis A. Sayre, who referred him to me.

He was in good general condition, though having twelve per cent. of albumin in his urine, which decreased to seven per cent. before I operated. The line of anæsthesia was sharply defined and above it no hyperæsthesia.

April 12, 1889, I operated with the assistance of Dr. Weir. The method pursued being typical I give it in detail and will not repeat it for the other cases. The back was shampooed the evening before and a damp sublimate dressing kept applied until the moment of operation.

The patient was laid prone but with one shoulder raised by a sand-pillow—favoring easier respiration and inclining the back toward the operator slightly. A free incision was made parallel to the spines, and a half inch to one side, cutting the longissimi attachments from one side only, and being carried clean down to the laminæ at the second or third pass of the knife. To approach the fracture between the eleventh and twelfth, the incision was made from the eighth dorsal to the first lumbar spine; the laminæ were then cleared of muscles, which were drawn outward by retractors, and the ligament divided above the spine of the eighth and below the eleventh, thus isolating a block of four spines, whose bases were then severed from their arches by stout cutting pliers.

This manœuvre at once allowed a retraction of the entire block of connected spines with their muscles still attached on one side, and the entire breadth of the spinal arch was thus exposed without sacrificing the overlying tissues. A pair of slightly curved rongeurs was then applied to the lower edge of one lamina and with incredible ease the entire breadth was quickly gnawed away. Three arches, the tenth, eleventh, and twelfth were thus treated and the clean spinal cord laid bare for two and one-half inches. The twelfth dorsal vertebra was found to have been displaced backward, the fracture running through the articular facets, the pedicles and laminæ. The cord was compressed between the arch of the eleventh above and the upper lip of the body of the twelfth below. The intervertebral cartilage had been ruptured. Above the line of pressure the cord pulsated, below it did not.

In half a minute after the cord was released from its flattened state (the bone pressure area being only half an inch deep) the dura became rounded up as full as it was

[1] A paper read before the New York Academy of Medicine, May 15, 1890.

above or below. When it was filled out there was no surface appearance by which one might say the cord within was not normal, except that the upper portion pulsated. I emphasize this because surgeons so often have reported that the cord appeared normal, therefore they did not open the dura. The wound now being irrigated and dried the dura was slit up for two inches. Adhesions of various densities were found within, attaching the meninges to the dura. They formed a complete circular dam, shutting off the upper from the lower part of the canal. Only an ounce of clear spinal fluid came out, as the spinal canal had purposely been inclined on the table so as to slope with the head lower. The veins of the cord were not distended. The adhesions were, with very little force, broken up.

The cord was normal in thickness above the involved part, then, by a sloping rather than abrupt change, it merged into a flattened cord for three-fourths of an inch, retaining its breadth but less than half its thickness, the principal atrophy seeming to be in the posterior columns. Throughout this flattened portion the white fasciculi of the cord could be traced continuously, so that there was no abrupt break in its continuity.

Before operating it had been proposed to the patient—whose unusual intelligence and thorough appreciation of his hopeless state enabled me to lay all the possibilities of spinal surgery up to that time before him—that if we found the cord destroyed within narrow limits and apparently sound above and below, we might excise the destroyed portion and suture the fresh cut ends, if in our judgment it seemed wise. Though told it had never been done he accepted the experiment. It proved to be an impossible operation, however, in his case. To judge whether it would ever be possible, I tried to approximate the sound cord on either side of the damaged part by traction made with tenacula, embedded in the meshes of the membranes at such points as would have been available for sutures.

There is a slight latitude of motion of the cord vertically in the canal, and I judged at this trial that I might have excised a scant quarter of an inch, and then approximated the ends by sutures that would not tear out. The damaged cord in this case was three times that length. No further repair being possible the dura was sutured by fine catgut. Then the displaced spines were brought into line and sutured by heavy catgut to their neighbors above and below.

The fascia investing the muscles then received two or three interrupted catgut sutures with gaps for drainage, and finally the skin was drawn partly together by a few catgut sutures not tied, but left for use at the next dressing. No drainage-tube was applied, but a piece of protective three inches wide laid over the wound, the skin edges being left a quarter of an inch apart so as to allow drainage from the deep portion. The investing antiseptic dressing was covered by a plaster jacket covering only the back, like a turtle shell, and secured by an enveloping canton flannel binder pinned in front.

In forty-eight hours the dressing was changed.

Drainage had been perfect; the wound had healed except the skin, which the sutures, already in place, now brought together when tied, and a final dressing was put on.

From the time of operation he had no pain in the back or extremities. The wound healed primarily, leaving only a linear scar. He remained three weeks in St. Luke's Hospital, with no fever or other disturbance. His condition has been watched since then, and there has been no improvement in motion or sensation.

For six weeks he wrote encouragingly, and claimed that he could draw up his toes an inch and had returning sensations. A recent letter, however, written nearly one year after operation admits that he has gained nothing. Yet in general flesh and mental welfare he has never been better, weighing more than ever, and enjoying life from his perambulator which he wheels about.

About six weeks after operation he passed through a curious two months' illness of the nature of trance. He writes me that he began by having severe pain in his feet and legs every morning, then became unconscious after two weeks and remained so, yet seeming to be in pain while thus sleeping. Soon he became calm and slept constantly, sometimes answering questions and sometimes not understanding; but he seemed to know who was about him, and would usually tell. He came out of this abruptly and was in every way mentally himself again.

I judge this to have been an effect left by reaction after two months of exalted excitement and harboring the "exhilarating sentiment of hope," followed by swift appreciation of the unchanged paralysis, and that it is only one of the curious hysterical manifestations occasionally connected with spinal disturbances.

CASE II. *Fracture; Paraplegia below Eleventh Dorsal, Two and One-half Years' Duration; Operation.*—G. W. I——, aged twenty-seven, merchant. In October, 1886, the patient was thrown from his horse on his ranch in Montana, and struck his back across a stick on the ground, injuring the spine at the junction of the dorsal and lumbar vertebræ. Instantaneous and complete paraplegia resulted below the waist, with paralysis of the rectum and bladder. He lay where he fell for a day and a half before he was discovered, during which time he was exposed to sleet and snow. When he was found he was taken to a farm-house and the nearest physician was summoned from a distance of ninety miles. During his exposure of a day and a half he had no food or drink. He had an over-distended bladder, but before the doctor's arrival he devised a method of his own for relieving his bladder by means of straws, the ends of which were rendered smooth by dipping in candle-wax. As a restorative after arriving at the farm-house, bottles of hot water were applied to his feet—so hot as to cause blistering, which resulted in gangrene. After three weeks he was removed to his home in Connecticut, where it was found necessary to amputate both legs below the knees. The bladder was catheterized for a week after the accident, but subsequently emptied itself when full without his control or knowledge. Rectal movements were also involuntary. Subsequently he suffered from severe sacral bed-sores. The paralyzed limbs often had a sense of burning and severe pain. Bending the knee forcibly caused pain, and at the time the legs were amputated, no anæsthetic being supposed necessary, the sawing through the bones caused intense pain.

His general health recovered so that he was able to be placed in his carriage and driven about. Indeed he was constantly in the habit himself of driving, of which he was very fond, being secured in the wagon seat by straps.

A few months before he came under my care, which was two and one-half years after the accident, he had unwisely remained in his buggy about seven hours. His anæsthesia rendered him unconscious of discomfort from prolonged pressure and there resulted a large area of pressure gangrene under each buttock. The resulting pressure sores refused to heal and thereafter he was confined to his back. His condition became so desperate that life had little in it for him, and he had even threatened to shoot himself if left alone. With the hope that some method of operation might be devised for his improvement he was brought to me at the Post-graduate Hospital by Dr. Smith, of Meriden, Conn. Examination showed absolute paraplegia and anæsthesia below the line crossing the sacrum at its upper border and extending in front across the abdomen two inches below the navel. The bed-sores under the buttocks were unhealed, exposing the bone. There was involuntary muscular jumping in both legs. Urine showed granular casts, but no albumin. The patient had strong and natural erections with emissions.

He was examined by Dr. Dana, whose conclusion was that the cord was absolutely severed at the last dorsal, but that below the second lumbar it must be in fairly healthy condition.

The case seemed absolutely hopeless unless it were possible to innervate the lower segment of the cord by renewing its contact with the upper, or, what seemed not impossible and perhaps worthy of trial, to carry out a suggestion of Dr. Dana's, in case the parts were not too much injured, "to cut off a few of the lower dorsal roots long and of the lumbar roots short and suture them together, thus increasing the chance of getting sensation.

The man's hopelessly bed-ridden and suffering condition led him to urge us to any operation, however novel or dangerous, that offered the slightest chance of improvement. I therefore operated, April 18, 1889, at the Post-graduate Hospital, by the same method as detailed in former cases. An incision was made from the ninth dorsal to the third lumbar vertebræ, and the spines of the tenth, eleventh, and twelfth dorsal and first lumbar were clipped from their arches and drawn aside with attached muscles, exposing the entire spinous arch. It was then found that a massive and dense eburnated deposit of bone had formed at the site of the eleventh and twelfth dorsal and first lumbar laminæ. This was with difficulty chiselled and cut away until the severed end of the spinal cord was exposed and found to be completely cut across and the dura sealed up. Below this, for one and one-half inch, solid bone filled the vertebral canal. The cord here commenced again and its end was found engaged in the bone so that spiculæ had grown into it. It could not be lifted up to approach the upper end more than half an inch, and it was evident repair by suturing was hopeless. The operation had been unusually bloody on account of numerous venous sinuses, which were opened in the bone and the patient was considerably exsanguinated. He rallied fairly well from the operation by thorough stimulation and saline infusion of thirty ounces into the vein of his arm, but died thirty hours after, the kidneys secreting only four ounces of urine during this time.

Case III. *Fractured Eleventh Dorsal Vertebra; Paraplegia; Operation; Opening Dura; Recovery Unimproved.*—J. S——, aged twenty-seven, coachman. On January 1, 1889, alighting from the rear platform of a "bob-tail" car, while going rapidly, he was struck in the small of the back by the platform, fell on his hands and knees, suffered acute pain in his back, and was paralyzed at once. He was moved in an ambulance to a hospital, and plaster jacket applied for a month. Had incontinence of urine and fæces. His urine was acid and contained a trace of albumin. Had no pain in his legs and paraplegia was complete. Admitted that he could feel when his legs were touched and complained of tingling in both feet and legs. On examination a slight depression was seen between the last dorsal and the first lumbar spines. A line of anæsthesia crossed the back at the top of the sacrum. At the sides it ran one inch above the crest of the ilium and crossed the abdomen two inches above the pubes, the line following the curvature of the groin along Poupart's ligament. There was atrophy of all the muscles of the thighs and legs. Complete paraplegia and anæsthesia, the skin of the lower extremities showing persistent vasomotor impressions.

February 28, 1889.—Operation under ether. Incision seven inches long from the ninth dorsal to the second lumbar. Operation essentially the same as in the case narrated last. The laminæ of the tenth, eleventh, and twelfth dorsal and first lumbar were removed by rongeurs. The arch of the eleventh dorsal showed evidence of recent fracture, but there was no displacement and no pressure. The dura appeared evenly full and round, and as far as its surface showed nothing would be suspected wrong within it. It was, however, then slit for three inches and a half; from the lower part a little fluid escaped. At a point underneath the injured arch a circular dam of lymph was found, one eighth of an inch wide, between the dura and the cord, entirely shutting off the upper from the lower part of the canal. From above this dam the arachnoid fluid flowed freely. The cord at this point showed evidence of having been completely crushed, the white substance ending abruptly and beginning again something over half an inch below. In the intermediate space the cord was represented by a pinkish-gray substance, apparently consisting of only the meshes of the membranes, but no white fasciculi. Just below the lymph-dam a mass of largely distended veins occupied the surface of the cord, showing obstructed venous return. These entirely emptied themselves upward when the pressure was taken off and the lymph parted by the probe. The cord was entirely liberated from its adhesions, the dura sutured with fine catgut and the wound closed.

The patient convalesced without fever, the temperature never rose above 99°, and the wound healed promptly with no escape of cerebro-spinal fluid. On the following day, I was surprised to find that the patient had acute hyperæsthesia of all the paralyzed part. A touch or pulling of the hair on the feet, legs, and thighs instantly gave acute pain and involuntary jumping of the limb. There was absolutely no voluntary motion however. He was able to identify the part touched, as witnessed by Dr. Dana and myself and the House staff.

During the second week, this hyperæsthesia abated, and he was as he had been before. The muscular response to Faradism was improved, but there was no volitional action up to six weeks after operation.

All operators upon cases of fracture paraplegia of any duration have thus far arrived at about the same conclusion—namely, that the pressure of bone is of the most secondary importance, except the fracture involves only the arch, where it is driven in by a blow, inasmuch as the violence, usually a fall and bending of the back, which will produce instant paralysis, has done so by a diastasis of the vertebræ, the cartilage being ruptured and the arches broken, which completely pulpifies the spinal medulla. The vertebræ are very apt to immediately resume their usual relations. If, however, the fracture takes place at or below the last dorsal, where the medulla has disappeared and the firm cauda equina commences, the crushing does not usually destroy the nerves, but long bone-pressure would. In such cases operation to correct it is always desirable. It still remains a problem, perhaps never to be solved, how to connect the lower segment of the cord with the upper when there is a gap of half an inch, and whether this union would restore functional connection with the brain, even though its reflex and independent activity may be ever so good. The cases may yet be found where sufficiently narrow transverse lesions will allow suturing fresh cut ends of the cord.

In other cases it remains yet to try the suturing of nerve-roots from above the break into some one or two below, sacrificing only the cutaneous supply for a small area, as suggested by Dr. Dana, or, as seems feasible, implanting them into the cut end of the lower stump, thus perhaps innervating some limited portion of the distal end with the chance of stimulating more. Possibly in this way even the vesical control alone might be restored. This is conjecture entirely, and based on the fact that clean-cut nerve-sections will unite.

The next case is one of Potts' disease, taken early and treated as a tubercular caries in any joint would be. The only points of interest are indicated in the report.

Case IV.—Eugene K——, aged twenty; glass-worker. This case is narrated simply to show the ease with which the vertebral bodies, if carious, may be approached from behind.

Two years before admission the man had had a pleurisy from which he recovered. Subsequently he was cured of a fistula in ano, and when he came into St. Luke's Hospital he had slight phthisical changes in the apex of the left lung, and a lumbar abscess prominent over the iliac crest. The latter was opened in September, 1889, by Dr. Curtis, and discharged profusely through three sinuses around the crest of the ilium.

In February last, I found a long probe passed upward to the last dorsal vertebra, and as there was no deformity

and but little pain, I considered the possibility of curetting the carious bone.

On February 5th I incised beside the twelfth dorsal, guided by the end of the probe. The transverse process of the twelfth was carious and was cleared away with a bone curette. This instrument was then worked into the body of the bone alongside the spinal dura, without injury to the latter, and a large excavation of softened bone removed to the extent of about half of one vertebral body, when on every side the curette encountered firm and apparently sound bone; the entire course of the pustrack through the soft parts was curetted and douched with sublimate solution, and finally with solution of iodoform in ether. The wounds were dressed with the usual care. In six weeks the patient was sent from the hospital with only a slight discharge, and with but one sinus.

The course of this case shows that where there are long sinuses connected with a small carious bone-focus the great proportion of purulent secretion is from the sinus walls, uniformly lined with tubercular granulation. It further illustrates the ease with which the excavation and drainage can be accomplished directly backward through one side of the vertebral canal, by pressing the uninjured dura aside.

I now speak of two cases of unusual interest, because they represent a field in which the extreme nicety of diagnosis does credit to the physicians in charge, and surgical relief follows closely.

Case V. *Extradural Tubercular Tumor of the Spine; Paraplegia Complete; Operation; Recovery.*—I epitomize the narrative of this case, which has already been reported in full at the State Medical Society in Albany one year ago, *New York Medical Journal*, February 24, 1889.

G. P——, aged twenty-two, was taken with pain in his back in January, 1888; came to St. Luke's Hospital in March. The spine was flexible, and without deformity, though a very slight fulness was seen in the soft parts to the right of the ninth and tenth dorsal spines. During March sense of touch was dull in his legs and the muscular power somewhat weakened. A line of hyperæsthesia formed about his waist. Two weeks later he could not stand without support and he had uncontrollable twitchings of the legs, which had become quite anæsthetic. He had constant intercostal pain, with girdle pains about the limiting line of disease. Incontinence of urine and fæces followed. An active hectic set in and he rapidly wasted away. During the week before operation he failed so rapidly that it seemed he could live but a short time.

On May 26, 1888, just two years ago, I operated. Making a free incision I removed the spines and arches of the eighth, ninth, and tenth dorsal vertebræ. Outside the carious arch of the ninth was a half ounce of thick pus, but within, and filling the vertebral canal, was a small quantity of inspissated pus and a large amount of dense neoplasm—evidently tubercular. It extended up and down the canal for two and a half inches and was thoroughly curetted from the cord by Volkmann's spoon until sound bleeding tissue was left on every side. The cord was firmly compressed against the anterior wall of the canal. The wound was lightly packed with iodoform gauze and allowed to granulate. A plaster jacket was applied over all. On the eighth day sensation began to return in his thighs. In three weeks he began to move his legs and toes. His hectic left him. Pain disappeared at once and appetite returned. In six weeks he moved his legs well. In three months walked with crutches. In five, walked without support, but with an ataxic gait. In eight had become robust and hearty and walked very well.

He resumed work and remained in perfect health for two years, walking as well as ever and without fatigue. Recently, after the confinement of the winter, he has had an abscess form in the cicatrix which had been so long healed, and I have had to curette a sinus remaining from it which led down to the bone. There has been no affection of the cord, however, and I hope very soon to heal the sinuses, though they have a distinctly tubercular appearance.

Case VI. *Pressure Paraplegia from Extradural Sarcoma; Operation after Eight Months; Resection of Arches of the Eighth, Ninth, and Tenth Dorsal Vertebræ; Complete Removal of Tumor; Death on Ninth Day.*—Professor D. A. MacG——, aged forty-two, of Toronto. The family history of this patient represents an unusually vigorous type and free of any inherited tendencies. He himself a man of excellent physique and with no acquired disease and enjoying exceptional health except for one incident, repeated eight or nine times during as many years, namely that he had vomited dark blood from his stomach, "not at any time more than a teacupful," and always after some particularly violent exercise, such as rowing, sawing, or shovelling snow, which caused kneading motion of his stomach. He never regarded the matter seriously and only once sought advice. The last occasion was one year ago.

Three years ago, while placing a pedal under a heavy piano, the instrument was let down and pressed heavily on his back. He suffered pain several days. Six months later, while lifting the corner of a piano he was caught by an excruciating pain in the back and felt as if he had stripped up a piece of muscle from the rib on his right side. No further pain or trouble ensued. About July 1, 1889, he jarred his spine severely, by attempting to spring upon a car platform, but miscalculating the distance, alighted violently on his feet, on the pavement. A week later he again jarred his spine by slipping on an icy place and plunging forward on his hands and knees. These are all the possible sources of trouble known to him. In July, 1889 he first felt a decided, though not severe, pain in his back at the site of the present trouble. His health began to decline. His bowels became difficult to move except by laxatives which it was found necessary to make stronger and stronger. As the days passed on he found it difficult to urinate and by great effort could only partially empty the bladder. A pain, mostly in the right side, centred in the back and a "trickling sensation worked about the line where the girdle of paralysis now is." He kept himself tightly bandaged to relieve pain. He was believed to have muscular rheumatism and as he was losing strength rapidly was urged to take exercise. In two weeks he found it painful to rise and dress, but by effort did so and supporting his back with both hands walked about the house. At the end of five weeks he found himself losing his ability to guide his limbs. His limbs grew weaker and he walked pushing a chair before him for security. He had no temperature, but from sheer weakness he took no exercise for several days. After again being told he must exercise, he made one final effort on the evening of August 23d. He pushed the chair before him but fell on his side. With indomitable will he made another effort and fell on his back. Then he crawled to a sofa and lay there all night. Immediately thereafter his paraplegia and insensibility were complete. One of his feet was blistered without his knowing it, and retention of urine required catheterization. During two months succeeding he recovered a little control of his bladder and improved somewhat in health.

In October, 1889, he was visited by Dr. E. C. Seguin in consultation. A diagnosis of pressure paraplegia was made, and operation advised. A letter from Dr. Seguin, which I will cite later, gives the ground of differential diagnosis. About January 1, 1890, he came to New York under the care of Dr. R. F. Weir. Drs. Seguin and Weir found on examination a slight fulness of the eighth dorsal spine, and advised a month or six weeks' orthopædic treatment, hoping that the pressure might be from Pott's disease, and that a natural relief of intravertebral pus might soon be expected and the paraplegia cured without operation. Dr. A. B. Judson adjusted a most comfortable spinal brace, and watched his course.

The looked-for improvement did not come. His cys-

titis grew worse. Absolute anæsthesia was established below the waist. The bowels, which had been constipated, became incontinent. He had a fortnight's illness with acute nephritis, and a temperature of 102½° F. Dr. Weir being now in Europe, he was transferred to my care, as he had directed in case of decline.

March 13th.—On examination his urine now had five per cent. of albumin. The anæsthesia line encircled the body, passed through the navel in front, the second lumbar spine behind, and a line at the sides three inches above the iliac crest. The muscles of the legs were in spastic contracture. The plantar, perineal, patella, and other reflexes were exaggerated. The eighth, ninth, and tenth dorsal vertebral spines were raised a little, and pressure on the right of them gave pain, as did pressure on the angles of the ribs on the same side. General condition fairly good for operation.

On March 20th, the day before it had been arranged to operate upon him, he had an unaccountable chill, with a temperature of 104° F. Prior to this it had ranged from normal to 100° F. His urine showed twenty per cent. of albumin and various casts.

On March 23d, another chill and profuse sweating. His stomach had rejected food, but soon improved. This attack lasted over two weeks before his temperature fell to normal. There were no pulmonary complications, but deep ulceration of the rectal wall was found, which he said had existed for two months.

This attack, as well as the one of six weeks before, was probably due to a slight septic infection from the rectal ulcer, which now healed under iodoform.

By April 16th he seemed again in fair condition to bear operation, though not nearly as well as before. Assisted by Dr. Weir and Dr. Farquhar Curtis, I incised from the seventh to the eleventh dorsal spines. The arches of the eighth and ninth, as well as the base of the spine of the eighth, were found somewhat crumbly and eroded by a softish dark growth, which disintegrated the bone where it pressed outward from the vertebral canal. The bone was unusually porous in the neighboring parts, not immediately involved in the tumor, and bled freely. On removing the arches of the eighth, ninth, and tenth vertebræ, and the pedicle of the eighth, a firm dark growth was found to fill the vertebral canal, compressing the cord to the left side and flattening it somewhat forward, so that it represented scarcely more than half its normal bulk. The tumor stopped abruptly at the ligamentum subflava above the eighth, and extended downward an inch and a half. It was readily removed by blunt dissection from the dura, which was left with a quite natural appearance. The growth bulged backward between the arches, laterally between the pedicles, which it softened, and forward into the body of the eighth vertebra, and at the side into the subpleural space. From all of these sites it was removed by Volkmann's spoon. The pleura could be seen to rise and fall with respiration.

Not a trace of pus suggestive of tubercular caries was seen anywhere. The wound was packed loosely with iodoform gauze. No plaster jacket was used. He endured the operation very well and was in excellent spirits for four days, when an occasional hiccough was observed. His wound was in perfect condition, and the packing being removed on the second day, the sides were allowed to fall together.

On the fifth day the hiccoughing became rapidly worse, and he vomited everything except a little milk. On several occasions he vomited a little bloody fluid, such as he had done in former years. His bowels were freely acted upon, and his kidneys were doing quite well, with only five per cent. of albumin in the urine.

Every measure was resorted to to check the hiccough and vomiting. It seems that he was subject to attacks of this at times, and was relieved by soothing his stomach with slippery elm water or gum arabic, both of which failed now. His vomiting continued also. By the eighth day the incessant hiccough and vomiting had exhausted him. His respiration became irregular, pulse intermittent. He became delirious and died on the ninth day. His temperature for the last four days was nearly normal. The muscles of the legs began to react to electricity on the fifth day, the gracilis first, and many others on the sixth day. No return of sensation or voluntary motion, however, ensued. A careful examination of the tumor was made by Dr. J. S. Thacher, who found it to be a round-celled sarcoma, without trace of leucocytes, giant-cells, or tubercular material.

Although this patient died exhausted largely by the hiccough, I suspect there was some morbid condition of the stomach like ulcer. No post mortem examination was permitted, except of the spinal cord exposed in the wound. This was found to have rounded up to nearly its full size during the nine days that had transpired since operation. The dura was quite natural, and on opening it the cord and membranes looked normal in color, form, and consistence.

Of these two cases, the first may be considered one of tubercular tumor, as that was the essential feature of it. In all probability it only involved the arches of the bone; after its growth in the canal it began to press on the cord. The neoplasm was dense cellular growth, not hypertrophied dura, for that was left when the former was curetted away. The subsequent course of events has left no doubt of its tubercular origin. MacEwen reports two similar cases. My second case is of such special importance, as illustrating the differential diagnosis between myelitis of the cord and pressure paraplegia of tumor, that I take pleasure in incorporating a letter just received from Dr. Seguin relative to that question, and feel that further comments from me are useless.

"23 Aborn Street, Providence, R. I.,
May 15, 1890.

"My Dear Abbé.—The diagnosis of compression myelitis was arrived at by deductive and exclusive reasoning. The dominant symptom, the 'signal symptom,' was the fixed side pain which soon became a lumbo-iliac (?) pain. Then followed a gradually increasing paraplegia, without atrophy (at first), but with great increase of the reflexes. The anæsthesia was secondary during the first few months.

"Now, this symptom-group (at the end of October, 1889) was suggestive of a myelitis in the involvement of the lateral columns; a spastic paraplegia *plus* anæsthesia. The anæsthesia served to exclude primary sclerosis of the lateral columns. But the initial symptom, the fixed side pain, has, we well know, a very restricted meaning. It is never present in myelitis, or in sclerosis of any system of the cord. It surely indicates an extra-cordal lesion, involving in some way the posterior root or the mixed root of the nerve which supplies the seat of the fixed pain. I call this the dominant symptom, because it serves to localize the lesion (or the chief and primary lesion) outside the spinal cord at a certain level. This being granted, the other symptoms, which are apparently more striking, viz., slowly increasing paralysis and anæsthesia (the latter subordinate), and great increase of reflexes, would surely point to the existence of a lesion outside the cord, producing steadily increasing pressure on this organ at a limited point or level, leaving a healthy segment of gray matter caudad of the lesion. The diagnosis turns upon the pressure of fixed pain in one side, and also, though with much less logical force, upon the comparatively slight anæsthesia, at a time when the volitional motor impulses were wholly arrested at a given level.

"A focus of central myelitis in the dorsal region would give rise to a paraplegia, with equal sensory or motor symptoms, but probably with greater sensory symptoms; and the side pain would be absent.

"Having established, easily, I think, the diagnosis of compression of the cord by a growing lesion, the further diagnosis, viz., that of the nature of the compressing lesion, is extremely difficult, and often impossible. In a case

which has exhibited external cancerous or sarcomatous tumors, the diagnosis of such a tumor of the dura or bones is not difficult. In cases where signs of pulmonary phthisis are present, or where there is a clear history of injury to the vertebral column, we are warranted in diagnosticating some form of 'Pott's disease' with caseous formations. In a syphilitic subject, the question of gumma of the dura mater should be considered. In cases without injury, or phthisis, or syphilis, or external tumors, we can only venture a diagnosis of primary tumor of the dura or bones by exclusion, but this is, after all, guesswork to a certain extent. Usually the tumor is not diagnosticated, as happened in the case of Commander J——, where I made a diagnosis of compression myelitis, *probably* from 'Pott's disease.' I do not include in this discussion those cases in which an evident large kyphos indicates the collapse of the bodies of several vertebræ from 'Pott's disease:' these are most easy of recognition.

"What I have said of the significance of the side pain will explain why I have always taught that great care should be taken to ascertain exactly whether the sensation in the patient's side (chest, abdomen, or groin) is a true pain, or a sense of constriction. The former has the specific value I have assigned it above, while the latter occurs in myelitis, meningo-myelitis, posterior spinal sclerosis, etc. Either of these symptoms may be uni- or bilateral.

"Let me add it as my deliberate opinion that in cases of compression myelitis, except when due to syphilis and 'Pott's disease,' *improving* under appropriate treatment, an exploratory or curative operation is justified, and should not be too long postponed.

"Sincerely yours,

"E. C. SEGUIN."

Finally, two cases of section of certain of the sensory roots of the brachial plexus for neuralgia present what I supposed to be a unique operation. Soon after its publication, however, the case of Mr. W. H. Bennetts, of London, was published—narrating a similar operation for relief of sciatic neuralgic spasm, by division of the posterior roots of the first, third, fourth, and fifth lumbar, and first and second sacral nerves within the dura. The man was at once relieved of all pain, though the spasms continued and anæsthesia of an extensive distribution in the leg resulted. In a few days this area renewed its power of sensation, though the pain kept in abeyance. On the twelfth day the man died of apoplexy.

This operation was performed on December 24th, and mine on December 28th.

CASE VII. *Intractable Brachial Neuralgia; Nerve-Stretching, Amputation, and finally Intradural Division of the Sixth, Seventh, and Eighth Cervical Nerves.*—This case was reported at the State Society meeting (*New York Medical Journal*, February, 1889) and will be epitomized here.

For nearly two years before I operated, the patient, a man, forty-four years of age, had suffered most intense neuralgia of the right brachial plexus, appearing in the forearm and hand. It began the night after a hard day's work putting a zinc lining in a large butcher's refrigerator. It grew worse and more paroxysmal. The hand became disabled and muscles somewhat atrophied. Dr. Dana and others agreed in the diagnosis of ascending neuritis.

Dr. Bull stretched the posterior interosseous and ulnar nerves in the spring following. The pain was no better. The patient begged an amputation, and in July Dr. Bull removed the arm at the deltoid insertion in the humerus. The pain did not abate. The fingers seemed to draw and twist as if still on. He acquired the morphine habit, taking a half-grain hourly to subdue pain.

The possibility of the pain being caused by a tumor or inflammatory process near the origin of the nerve-roots, or of dividing the sensory roots behind the ganglion, as proposed by Dr. Dana, who referred him to me, led to the following operation:

On December 31, 1888, I removed the arches of the fourth, fifth, sixth, and seventh cervical vertebræ and exposed more than two inches of the cord. No tumor or abnormality was felt. I then drew back the roots of the sixth and seventh nerves from the intervertebral foramina into the vertebral canal, made some electrical observations detailed in the previous report, and then cut them across just outside the dura where sensory and motor roots join. The wound was lightly packed with gauze.

Recovering from anæsthesia, he still suffered pain, seemingly in the fingers. This region was supplied by the eighth cervical nerve. Forty-eight hours after the operation I placed the patient prone, under a good light and without anæsthetic, removed the gauze packing and did the following operation: The dura and cord lay in the bottom of the wound clean and dry. I punctured the dura and split it for an inch and a half, letting out two ounces of spinal fluid. This was painless and produced no appreciable sensation upon the patient or effect upon his pulse.

I now picked up the posterior roots of the eighth nerve within the dura which was at the same level as the seventh outside, and cut a quarter of an inch from it. It gave him exactly the same pain when handled as he had experienced for two years or more, and I hoped we had at last gotten at the root of the trouble. I treated the seventh nerve likewise. Then sutured the dura with fine catgut and closed the entire wound. Immediate union was obtained, better even than by primary suture, and a fine linear cicatrix remains, as you see, upon the patient's neck.

The pain entirely changed in character, though he had considerable pain for the next ten days. It no longer went down into the fingers, but seemed to draw the stump. After eleven days he sat up and stopped his morphine. Pain was even less after this. Yet it was paroxysmal and at times severe. The skin was anæsthetic, completely so, from the acromion process downward on the entire outer sides of the arm. There was partial anæsthesia of the anterior and posterior aspect of the arm and over the shoulder from the middle of the clavicle to the middle of the scapula, while the skin facing the axilla was rather hyperæsthetic. This condition was maintained unchanged up to the present, a year and four months since operation. Another disturbance is of interest. Since the fourth day after the operation the vaso-motor disturbance is shown in the anæsthetic skin, which when pinched remains blanched for two or three minutes and when pricked or scratched becomes suffused and forms wheals persisting ten or fifteen minutes. This condition still maintains. He now thinks he has as much pain as before the operation and has gone back to taking a grain of morphine daily.

CASE VIII. *Intractable Brachial Neuralgia Intradural Division of the Posterior Roots of the Sixth, Seventh, and Eighth Cervical and First Dorsal Nerves.*—Gabriel Z——, aged forty-five. Patient gives no history of rheumatism or syphilis, but has had malaria at one time.

In the latter part of 1886 he states that he exposed his arm at the window of a street car while he was in a perspiration and he dates the beginning of his trouble from this time. A few days afterward he experienced sharp pains between his thumb and index finger. This grew steadily worse and at length became located on the outer side of his forearm and was accompanied by a feeling of drawing and twitching of the little and ring fingers as well. The pain extended up the forearm. It was intermittent, but of such severity as to cause him to cry out.

After two months he grew weak and nervous, lost his appetite and suffered so much that he had to give up his business.

The attacks were paroxysmal and the sensation described by the patient was that of a "drawing pain," the acute seizure leaving some continuous pain and soreness on the ulnar side of the hand and arm.

In August of the following year his ulnar nerve was

stretched by Dr. L. A. Stimson. The pain grew steadily worse, the attacks coming on more frequently at intervals of half an hour. The pain spread over the forearm and hand, and in July, 1888, the ulnar nerve was exsected by Dr. Fluhrer. Following this the pain recurred in an exaggerated form, and the nerves of the brachial plexus were stretched in the axilla by Dr. Gerster. The paroxysms became even more severe, coming on every five minutes during the day and every half hour in the night.

After the first operation the forefinger became drawn backward and the forearm wasted. The patient took to morphine in large quantity with only temporary relief.

On February 9, 1889, the patient came under my care. Examination showed him to be a rather intelligent man, of spare physique. He bears evidence of long suffering and has a haggard expression. His attitude is peculiar; he sits with his head bent forward and his body bent so that his left elbow rests upon his knee, his right hand grasping his forearm, the elbow semiflexed.

At intervals of a few minutes he is seized with violent paroxysms of pain which he describes as of a "drawing" character extending from the fingers up the forearm, as though his fingers were being drawn away from his hand and his hand from his forearm. He has a habit of shouting with these attacks of pain, which have made him a source of dread in the neighborhood of his residence. Grasping his arm he will walk the floor in agony for from three to five minutes until the pain subsides. The night attacks are similar to those of the daytime, although not so frequent. Sleep is of course only fragmentary. Urine showed specific gravity 1.009, no albumin.

The flexor actions of the hand are very feeble. The intrinsic muscles of the hand are atrophied, the thumb and middle finger being constantly in a sweating condition. He can raise his hand to his head. The deltoid is atrophied. Triceps in good condition. Infraspinatus atrophied.

He requires hypodermics of morphine about every two hours to render him at all comfortable—one-sixth of a grain.

On consultation it was thought possible to bring about sensory anæsthesia by operation upon the sensory roots of the brachial plexus.

On February 15th, the patient was etherized and I operated, assisted by Dr. Murray. The neck was shaved exposing the occipital protuberance, and the patient was placed in a semi-prone position on his right side. Incision was made to the left of the spinous processes from the third cervical to the second dorsal vertebra. The laminæ of the fifth, sixth, and seventh cervical and first dorsal vertebræ were cut away, exposing the dura. Palpation revealed no tumor or abnormal condition of the cord. The dura was punctured and an ounce of arachnoid fluid escaped. The dura was then slit up for two and one-half inches. The cord appeared normal except that it was slightly congested. The posterior root of the first dorsal nerve was then lifted with a strabismus hook and divided by scissors close to the cord. The free end was then caught by mouse-tooth forceps and one-quarter inch was exsected. The sixth, seventh, and eighth cervical roots were similarly treated. The dura was then sutured with fine catgut. After suturing, the seventh and eighth cervical nerves were then stimulated by a weak faradic current outside the dura, Dr. Dana assisting. Stimulation to the seventh resulted in sharp muscular contraction, the scapular being jerked upward and the arm rotated inward. Current applied to the eighth caused the forearm to be sharply extended.

The wound was then sutured with deep and superficial sutures.

On the following day the patient passed a very comfortable time, using less morphine.

On the second day he had but one hydodermic and slept two hours, taking his nourishment well.

The third day he complained of pain in the shoulder and arm, but had a fairly comfortable day and slept for four consecutive hours.

On the fifth day he had severe pain in his head and some mental excitement; took nourishment well. This day there was recurrence of his sharp attacks.

On the seventh day wound was dressed and he was more comfortable. He was allowed to get up, as it was found impossible to keep him quiet in bed.

On the eighth day he suffered less from pain.

From the ninth to the fifteenth day the old pain continued, though less severe.

At the end of four weeks the patient was discharged in a condition of moderate improvement in the matter of pain.

The morphine habit had been entirely checked.

Two months after the operation I visited him at his house. He was much improved in general condition and doing well. He still maintained the habit of leaning his head down and seemed to be in pain. He was, however, easily diverted, and if entertained seemed free from paroxysms for considerable intervals. His actions suggested those of a man craving attention and gave me the impression of one desirous of continuing the appearance of suffering. He had entirely stopped the morphine habit and had stopped crying out as formerly.

Examination showed the arm and shoulder appearing as before. The muscular power was unchanged. Anæsthesia seemed complete on the left hand, front, and back up to an inch or two above the wrist, over the entire dorsum of forearm and side and dorsum of upper arm half way above the elbow to the shoulder. Above the middle of the arm to the shoulder there was no anæsthesia.

Dr. F. H. Strong, of Yonkers, under whose care this patient had long been, wrote me that he found him decidedly better, and that he thought the amount of physical suffering which he really felt was now comparatively insignificant.

Soon after this the patient had a severe attack of diarrhœa, and lapsed into a low muttering delirium, showing no evidence of pain while in this condition. For one month he continued to have delusions. He then improved rapidly and commenced having pains in the wrist, though not as before.

Two months subsequently he began again to suffer pain and howled during the paroxysms.

Three months after the operation his mind was perfectly sound, but he complained again of his pain and was despondent but did not scream out.

The subsequent course of his trouble during the year has been a mild type of the same evidence of pain as before the operation. The pain does not now cause him to shout. The anæsthesia remains the same.

Dr. Thacher's pathological report of the resected roots, says: "Inflammatory exudation quite marked at portions of the surface and less marked at a few points inside some of the roots. The changes are most marked in and around the root of the first dorsal."

The basis for this operation is the fact that sensory conduction is isolated in the posterior root, which is easily operated on within the dura. Experiments recently made by Singer, Horsley, and others, to study the ascending degeneration after this section in monkeys, showed that a speedy and complete degeneration backward into the cord followed the section. This would give the desired destruction of an inflamed or diseased nerve to its very ultimate fibres. In my two cases there has remained all the anæsthesia obtained at the operation. Pain, however, has apparently recurred, though much milder. There is often simulated pain in those who have acquired the morphine habit, but in these two cases I believe it to be genuine. My conviction is that if all five roots had been cut the chance of recurrence would have been less.

It is of interest that in four of the eight cases about two ounces of spinal fluid were evacuated when the dura was cut, but that no disturbance followed. These all recovered. Horsley says the dura is highly sensitive, and that the patient should be deeply narcotized when it is

cut. That this is an error is shown by the man who endured a two-and-a-half-inch cut in it without anæsthetic and told me at the time that it was painless.

I cannot end this paper without emphasizing the advantage of the method of operation I have adopted. It is the most speedy, the least bloody, preserves *all the tissues* in and about the spines which are replaced and give firmness to the back as well as preventing a gap that nature must fill.

The incision should be on one side of the spines only, they being cut off and dragged to the other side, exposing the entire arch without dividing the inter-spinous ligament. The only bone-cutting instruments to be used are two narrow rongeurs, one curved, one straight, with a quarter-inch bite and presenting a flat Gothic arch aspect when the points are brought together. Any saw is dangerous, awkward, and inefficient. The rongeurs are by far the quickest.

While we are not warranted in taking a sanguine view of the results of operation, yet surgery, with its possibilities ever looming up, ought not to occupy the ultra-conservative ground of the past in this field.

The scope of operative work may never be a large one, but it will probably not be as small as heretofore.

SOME PRACTICAL POINTS IN THE HISTORY AND MECHANICAL TREATMENT OF FRACTURES OF THE FEMUR.[1]

By J. H. HOBART BURGE, M.D.,

SURGEON TO LONG ISLAND COLLEGE HOSPITAL; CONSULTING SURGEON TO ST. JOHN'S HOSPITAL, BROOKLYN.

I HAVE no new method to propose, no display of apparatus to make, no exhaustive or exhausting essay to detain you with. When I entered the ranks of the profession the generally adopted method of treatment of this injury was by Desault's long splint, with the screw of T. Hewson Bache, by which to make extension, while a padded strap, passing between the limbs of the patient and fastened either to the head of the bedstead or to the upper end of the splint, served by pressure upon the perineum and groin to act as the means of counter-extension. This description carries us back nearly fifty years—even a little beyond the time of the simple and efficient device of applying strips of adhesive plaster to the sides of the limbs, by which to make the extension. Very few, if any, of you gentlemen are old enough to remember the difficulties, annoyances, and distresses which often attended the very best method of treatment in those days. So impressed was the elder Mott by these considerations that he said, "Should I chance to have a fractured thigh, I would prefer to be treated on the double-inclined plane," and many cases were so treated, not because of some peculiarity which demanded the flexed position, but simply to avoid the pains and annoyances of the other method. I need not take many minutes to tell you what these trials were. Remember we had no method of extension except the screw, and some sort of tie about the ankle—bandages, silk handkerchiefs, laced shoe, etc. Oh! the fatigue, the stiffness and pain of the ankle, and the frequent necessity of relaxation. Again, no screw could perform the duty of extension, unless it were watched continually, for all dressings and bandages relax speedily. Then, the padded strap pressing on the groin was not only irksome, but frequently caused deep ulcerations, necessitating its removal at all hazards. The elegant Professor George T. Elliot broke his femur in that epoch, and so determined was he not to have a shortened limb, that he suffered most heroically this procrustean method.

Previous to the introduction of the screw for extension, which I find mentioned in Brinton's Erichsen, 1854, the foot and ankle of the patient were tied to the lower end of the long splint, and the elongation of the limb effected only by pressing the splint toward the foot of the bed, and tightening the counter extending strap. The first great relief came when Josiah Crosby, with his Yankee shrewdness, made the strip of adhesive plaster do the pulling for extension, to which I have already alluded. The traction being from so large a surface, and the plaster being kept so nicely in place by the roller bandage and by the pressure of the side splints, the improvement over previous methods can only be imagined by those surgeons who came upon the stage later.

Still the screw—the worst feature of all—was retained. About this time my brother, Dr. William J. Burge, and I introduced to the profession an apparatus for the treatment of this injury. I will not describe it here. We have reason to feel highly gratified with its record at the New York Hospital, at Bellevue, and elsewhere. No such series of results had ever been published. Though the number was not large, the cases were sufficiently varied, and were under the inspection and supervision of the most vigilant surgeons. Among these were Drs. Valentine Mott, Frank H. Hamilton, James R. Wood, Gurdon Buck, John Watson, Willard Parker, E. Krackowizer, Zina Pitcher, Stephen Smith, and many others.[1] Dr. George F. Shrady, whom we all know as the able editor of the RECORD, was at that time house surgeon to the New York Hospital, and I take pleasure in referring to his impressions of our apparatus as written by himself in the *New York Journal of Medicine*, 1859, p. 383. You will naturally ask, "If this apparatus was a good thing, why is it not now in use?" Please remember that we were still handicapped by the pernicious screw, and though I characterize by such a title, even this was an improvement upon what had gone before, and still was not so universally known or acknowledged as to prevent Dr. James Spence, of Edinburgh, from publishing a work on surgery in 1871, in which not a word is said of any improvement upon the methods of Desault, Pott, Liston, and McIntyre.

There were, however, some features in our apparatus which we regard as of great value—the only one which I desire to speak of now, as related to my present purpose, was the attachment of a counter-extending strap to some point perpendicularly in front of the patient—between the pubes and the ceiling, so that it should not press upon the groin. This we effected by a bar across the bedstead about a foot above the body of the patient. So essential did we regard this apparatus to the best treatment of these fractures at the time of its introduction that we, at great personal inconvenience, undertook to direct its manufacture and to supply those surgeons who desired it.

Very soon after this the weight and pulley took the place of the screws. It seemed to come not as the invention of any one man, but as the most successful of all the experiments which were being tried by many surgeons about that time. In these experiments the surgeons and the internes of the New York Hospital were especially active, and none more so than Dr. Gurdon Buck, whose name is ever honorably associated with this last and greatest advance in the treatment of these injuries, not because of any claim to originality, but because he knew and recognized and popularized a good thing when he found it. I was surprised in looking over the private correspondence of Dr. F. H. Hamilton, as reported in the "Transactions of the American Medical Association," vol. x., to see a letter dated 1857, in which Dr. Joshua B. Flint, of Louisville, Ky., says, "I have used, and with much satisfaction in the fractures to which you refer, extension by means of the pulley, . . . with more comfort than attends any other equally effectual method of extension. I am more surprised when I reflect that it was several years later when the weight and pulley became general. The substitution of the weight and pulley for

[1] A paper read before the Brooklyn Surgical Society, April 16, 1890.

[1] See Hamilton's Report to American Medical Association, Transactions, vol. x.; also Hamilton on Fractures and Dislocations, New York Journal of Medicine, 1857 and 1858.

the screw so simplified the whole appliance that we felt justified in declining any longer to furnish our apparatus as an article of manufacture, especially as the principles involved in its construction could easily be extemporized by any good surgeon. The next phase in the history of this subject I regard as a most unfortunate one.

With the weight and pulley came a growing indifference to counter extension, and a disposition to depend for this upon the weight of the patient's body. The counter-extending strap, which the new method of extension had rendered tolerable, was strangely and very generally discarded, and every surgeon finding that his patient was continually slipping down in bed, more and more in proportion to the weight employed for extension, it was quite natural that raising the foot of the bed from four to ten inches should become almost universal. All this is as familiar to you as to me, but possibly I have observed the effect more accurately than some of you who have seen only the later practice. I am confident that laying aside the counter-extending band has resulted in an appreciable loss in the average length of the limbs that have been so treated. I am confident that raising the foot of the bed, is not only useless but deceptive, and therefore injurious. I am not prepared by any measurements for a careful comparison between the results of the old and the new methods—such measurements would obviously have been hard to get, and very unreliable. Besides, the propositions I make are demonstrable without them.

First, then, as to the body of the patient as a dependence for counter-extension. When you apply a weight that causes any serious discomfort the patient will work himself down in bed till your effort is neutralized, and, second, when he has made a firm resting place for his hips, and you apply ten, twelve, seldom fifteen, more seldom twenty pounds, you will generally find that the limb below the fracture weighs more than that, especially with the dressings, and consequently that no extension is made, one weight only balancing the other. Let me invite you when you have a case put up in the most approved modern style, to go to the patient quietly, and uncovering the limb sufficiently to observe the effect, raise carefully and slowly the entire weight of extension, in such a manner as not to attract his attention or to cause any spasmodic action of his muscles, and then tell me if there is the slightest retraction of the limb. By this simple inspection I think you will be convinced that the weight employed for extension is seldom more than enough to balance the weight of the limb below the point of fracture. Whether the foot of the bed is raised or not, the patient begs for and gets pillows enough to make him comfortable and settling himself into the mattress his body not only does not act as a counter-extending force but is, as you all know, everlastingly slipping down in proportion to the weight applied and the amount of discomfort produced thereby. Of course you have him pulled up, only to repeat the operation at your next visit. I have studied the effect so thoroughly that I heartily advise the restoration of the strap for counter-extension—attaching one end either to the upper extremity of the long splint or to the head of the bedstead, and the other to some fixed point above and in front of the patient's pelvis. Keep not only the bedstead, but the mattress level, and watch carefully the length of the limb and the effect of your extension. After the unreliable screw with its alternate overstrain and understrain was discarded, there was really no reason for dropping the counter-extending strap—all its painfulness was due to the screw, from the effect of which, when it was tightened, there was no escape until by wriggling and twisting the patient succeeded in rendering it of no avail till the surgeon came and wound him up again. *Now*, with the gentle and steady pull of the weight, the limb is effectively elongated, the perineum and tuber ischii strike the counter-extending band, and the body can slip down no lower. If the pressure become at all irksome the patient can draw himself up in bed and relieve it without the slightest harm, the weight and pulley making it certain that when the pelvis reaches again the level of the strap the lower fragment will have been drawn down as fast as the upper descended. This is not theory it is common sense and matter of daily observation.

But it is quite possible that some may question my premises, and may ask to be assured that the method of counter-extension for which I so strenuously plead has ever been to any great extent neglected. I hardly need do more than appeal to the personal observation of the last twenty years of those whom I now address. Dr. Stephen Smith, in his work on "Operative Surgery," advocates the weight and pulley, depending on the weight of the patient's body, with the foot of the bed raised from four to ten inches, *or* upon the perineal band for counter-extension, plainly leaving it to be inferred that he considers either plan efficient but gives the preference to the first mentioned.

Dr. Frank H. Hamilton, who has for more than thirty years been considered by almost everybody the highest authority on all questions pertaining to fractures, and whose words have doubtless ruled the practice of the great majority, says: "At Bellevue, where we use the weight and pulley a good deal, I seldom employ the perineal band as a means of counter extension, except in the case of children, relying *altogether* upon the weight of the body for this purpose, the foot of the bed being elevated always about four inches." Hamilton, in "Fractures and Dislocations" (1866), p. 416, and six years later, in his "Principles and Practice of Surgery" (1872), pp. 290, 297, 298, pictures the weight and pulley, leaving out of the illustration and the text all reference to any counter-exertion other than that which the weight of the body might produce.

One word in reference to the use of the perineal band. Holmes's "Surgery," p. 617, 1861, recognizes the importance of fastening one end of this band in such a manner as to avoid pressure on the groin. This was first done by Burge's apparatus in 1857, and several years later Dr. F. T. Lente, of Cold Spring, introduced a special splint mainly to effect the same object.

There are two historic facts which I desire to speak of as having an important bearing upon the subject before us. You are all aware of the valuable service which Professor F. H. Hamilton rendered to science in his report on the results of fractures,[1] showing that the average shortening in cases of oblique fracture of the femur in the adult, even in simple cases, was little less than an inch. Before that report was made surgeons generally felt that their reputation was more or less at stake if they failed to get a full length limb after treatment for this accident. I do not wish to intimate that any surgeon would, because of this knowledge, relax his effort to obtain the best possible result. The point which I desire to make is that this knowledge came just at the time when the screw was discarded and the weight and pulley substituted, and that this unparalleled improvement in the treatment of this fracture, although conducing immensely to the comfort of the patient, lost most of its advantages by the simultaneous neglect of the counter-extending strap and pad, and that the new knowledge acquired through Dr. Hamilton occasioned a general satisfaction with results which a few years earlier would have given rise to great anxiety. I do not take issue with Dr. Hamilton. I know that, as a rule, a shortening of three-fourths of an inch, in an oblique fracture of the femur, in the adult, is not a bad result; but I would warn, especially the young surgeon not to be satisfied with such measurements. We should strive to get full-length limbs, and surely with the present facilities we ought to succeed in approximating such a result oftener than was possible in the earlier days to which I have referred.

The other historic fact which I alluded to as having some special relation to this subject, is the discovery and demonstration by Professor Jarvis D. Wight, of this so-

[1] Transactions of the American Medical Association, vol. x.

ciety, that the long bones are not always, or even generally, of corresponding length on the right and on the left of the same individual. This is now, I believe, universally conceded, and I am sure none of us will doubt the value of this discovery, nor fail to avail himself of its application, if he chance to have a broken femur to treat which was originally three-fourths of an inch shorter than its fellow. It is said to be "a poor rule that won't work both ways." Let this knowledge, then, be an incentive to greater vigilance, lest the result of a fracture increase, on the one hand, a previously existing disparity, or, on the other, unnecessarily convert the longer into the shorter limb.

A CASE OF TUMORS OF THE FOURTH VENTRICLE WITH LEFT ANOPHTHALMUS.[1]

BY HENRY D. NOYES, M.D.,

AND

CHARLES L. DANA, M.D.,

NEW YORK.

NOVEMBER 3, 1888.—Alphonse K——, aged thirty-seven, German, fresco-painter. Father died at age of sixty-four of some chronic throat trouble, sick for one year; mother died of carcinoma of uterus; two brothers died of infantile diseases; of two sisters, one died of typhus fever, the other in childbirth; three brothers living and in good health. Had diphtheria six years ago and was sick for a long time with it, no paralysis as a complication; had traumatic pleurisy one year ago in left side with effusion in chest, was sick for six weeks; has had no other sickness, no rheumatism, syphilis or malaria. In the month of January, 1873, was taken with severe headache, lasting for twenty-three days, when all headache went away and did not return until last February (1888). After the headache of 1873, began to see badly with left eye, the centre of field of vision appearing dark. This spot of darkness increased in area until 1875, at which time, being almost blind in that eye, under advice he had the eye enucleated and in it was found a large cysticercus cellulosæ. After the operation he suffered no more until last February, when he began to have headache of similar character to that of 1873 and in same part of head, that is, on *left* side. Since then has also had it on right side. The attacks of cephalalgia are intermittent, lasting usually four or five days and occurring in the forenoon; they are never absent longer than a week. A laxative usually relieves the headache. Since last February has been troubled with dizziness and roaring in both ears and numbness and tingling in right hand and arm and lately in right leg, though only to a slight degree; has felt weaker on that side. Worked up to last April, when weakness in right hand became so marked that he could not use a paint-brush without dropping it and gave up work. Says he never falls, though he staggers and is usually dizzy. Two years ago he fell down suddenly one day, striking on his head, was unconscious half an hour and was taken to a hospital, but went home the same afternoon and suffered nothing referable to the accident afterward.

Status presens (November 3, 1888): Patient is a well-nourished man. His left eye was enucleated in 1875, as above stated, by Professor Foerster, of Breslau, because of a cysticercus in the vitreous. He has paresis of the right rectus internus. His vision is normal, both for distance and near; field normal for colors and white light; pupil contracts in accommodation and on exposure to light; the ophthalmoscope shows the media and fundus to be normal. Hearing normal. Pulse, 80; temperature, 98° F. under the tongue. He distinguishes the two points of an æsthesiometer at 3 mm. on the fingers of both hands. Patellar reflex exaggerated on the right side, normal on the left; sensation conducted with normal rapidity. Dynamometer 65 with right hand, same with left. He states that he feels pain in the left occipital region when he squeezes the dynamometer with his right hand, but that there is no sensation when he uses his left hand. There is moderate complaint of pain when the left occipital region is tapped with the finger. He can move either leg easily, but when he walks quickly the right does not seem as well under control as the left; the step is shorter. Quick movements, either in walking or while sitting, are followed by attacks of vertigo which last about half a minute. His headaches are not continuous, but last about half an hour; he states that he sleeps only about two or three hours in the twenty-four. Stands with difficulty with his eyes closed; falls to the right side when he attempts to stand on the right foot, and with less promptness when standing on the left foot. Taste normal; appetite good; bowels move only by help of medicine; mind clear; temperature, $98\frac{5}{10}$° F.; pulse, 80.

November 5, 1888.—His vertigo has been severe. When standing he makes a motion with his toes as if trying to grasp the floor; headache is severe. Can walk only a short distance unsupported. Ordered iodide of potassium (which he has been taking for several months) and mercurial ointment.

On November 13, 1888, was admitted to New York Eye and Ear Infirmary where some of the above facts were elicited and was discharged November 17, 1888.

November 23, 1888.—Patient admitted into Bellevue Hospital, from the records of which institution part of the above history was taken. Patient says that his weakness and numbness are now more marked than formerly; bladder and rectum not invaded. Sensation and reflexes apparently not affected; both sides similar. Patient has been a drinker for years, but never to excess; been a moderate smoker. Has never been much exposed to varying degrees of temperature or to wet; has had no injury, except the fall of two years ago and blow on side fifteen months ago. Has been a painter for twenty-seven years. Does not remember having had an attack of painter's colic. Patient's gait at present time is that of a drunken man, though the staggering is chiefly to the right side, being of so-called "compelled" character; no rotatory movements. Attempts to turn to right side not so effectual as to left side. Discharged from Bellevue Hospital January 7, 1889.

January 13, 1889.—Patient came to the office of Dr. Cocks this morning assisted by his wife. His headaches and dizziness are less. He complains of a burning sensation in the right side of the face. Nystagmus, vertical and rotatory, is present. The external rectus of the stump of the left eye is paretic; fundus normal; V.O.D. $= \frac{20}{40}$; Jaeger 1 at 12 inches. Dynamometer, left hand, 63; right, 70.

January 31, 1889.—Patient, assisted by a friend, came to office. Paresis of both externi; right externus stronger than when first seen. Eyes move up and down; pupil reacts to light and in accommodation. Nystagmus more marked. No headache, but vertigo and want of co-ordination much more marked; speech thicker; swallows with great difficulty; left masseter weaker than the right; left temporal atrophic, so that the zygomatic arch is more marked than usual. Uvula hangs normally; has nasal catarrh. Pulse, 104; respiration, 20; temperature, $98\frac{1}{2}$° F. V.O.D. $= \frac{20}{200}$; fundus normal.

February 11, 1889.—Patient can walk only with assistance. V. $= \frac{20}{100}$; fundus normal; nystagmus marked. The movements of the eye are such as would be produced by contraction of the superior oblique. All objects seem to him to be moving. Absence of smell, and taste very much blunted. For the past eight days he has had the same sensations in the left side that he had one year ago in the right side; that is, pain in the end of the fingers, also in the back of the leg, knee, and foot.

February 12, 1889, 4.30 P.M.—Patient readmitted to Bellevue Hospital. At 9 o'clock of the same day had a convulsion, epileptiform in character, with both clonic and

[1] Read at the meeting of the New York Neurological Society, March, 1890.

tonic spasms. Conjunctival sensation present during the attack. No preceding aura and no frothing at mouth, no biting of tongue. Breathing arrested during tonic spasm, heavy and profound afterward, but not stertorous. No relaxation of sphincters. Says he had a similar attack on the forenoon of same day. Before and after the convulsions, which lasted about five minutes, patient showed marked vertical nystagmus, the movements were constant and more marked after convulsion.

February 13, 1889.—Patient having retention of urine from impassable traumatic stricture, about which no account had been given, was transferred to surgical division and operated on at 10 A.M. of the same day by perineal section. The retention of urine had existed for more than twenty-four hours. When admitted February 12th, could not walk without assistance, staggering was marked; much headache, dizziness, and tinnitus aurium.

February 16, 1889, patient died.

Autopsy revealed nothing to cause death from perineal section; heart, lungs, liver, spleen, and kidneys normal. Serous and mucous membranes healthy with the exception of evidences of old pleurisy. Brain showed three tumors in floor of fourth ventricle (Fig. 1) exerting some pressure on left middle peduncle of cerebellum. Sinuses and ventricles normal. Slight pachymeningitis interna fibrosa.

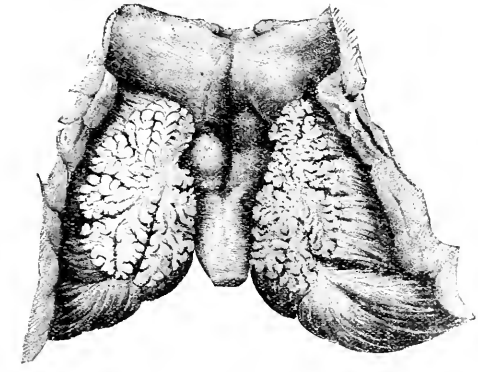

FIG. 1

The left optic nerve was very much smaller than the right, the former measuring 2 mm. and the latter 5 mm. in transverse diameter.

The optic tracts were very nearly equal in size, but the left was a trifle larger than the right.

The external geniculate body on the left side can hardly be made out, that on the right seems smaller than normal. There is post-mortem softening about the cerebral peduncle and neighborhood of the left external geniculate body, which may account for its non-appearance.

The two corpora quadrigemina anterior are of good size (6 mm. wide) the left apparently a trifle smaller.

On the floor of the medulla are three tumors, each about 16 mm. in diameter, arranged as follows: One is on the right and the other two on the left of the median line. That on the right is more anterior and extends from the middle of the pons to the posterior corpora quadrigemina. Of the two on the left side, the lower, larger, and more prominent extends from near the calamus scriptorius to near the level of the edge of the pons. It is intimately united with the third tumor, which is smaller and lies deeper and extends into the left half of the pons and middle cerebellar peduncle, and up almost as far as the posterior corpora quadrigemina.

Sections show that the tumors are well defined, but slightly infiltrating, and are rather superficially placed in the floor of the fourth ventricle. They are about 16 mm. in diameter and are sarcomatous in character.

A study of the occipital lobes shows them to be of nearly the same size.

Examination of Occipital Lobes.

Measurements.[1]	Right occipital lobe.	Left occipital lobe.
	Ctm.	Ctm.
Parieto-occipital fissure to posterior tip of lobe	6.5	6.5
Right cuneus to posterior boundary	4.0	3.5
Superior boundary	3.2	3.0
Inferior boundary	3.3	3.5
Circumference of occipital lobes around anterior occipital fissure and parieto-occipital fissure	18.0	18.0
From anterior occipital fissure to tip of occipital lobe posteriorly	7.0	6.0

Microscopical Examination of Sections of Medulla, Pons, and Ganglia (Staining by Weigert's Method).—1. *Level of Lower Edge of Olivary Bodies.* Degenerative infiltration of central gray matter, especially on left side of central canal. Internal and external arcuate fibres on the left side deficient. A triangular patch of degenerated fibres in the ventral part of the interolivary tract on left side, extending laterally toward the olives. Left pyramidal tract sclerotic to some extent. Ventral part of raphe imperfect. The nuclei of twelfth nerve well defined.

2. *Level of Middle of Olives.* The infiltration affects the gray matter of the floor of the ventricle of the left side, and especially the neighborhood of the nucleus of the column of Goll. Degenerated fibres run in the external and internal arcuate fibres to the triangular patch in the interolivary tract. The ascending root of ninth and tenth nerves (solitary bundle) on the left side contains degenerated fibres. The left motor tract contains degenerated fibres. The twelfth nerve nuclei are still distinct. The raphe is poor in fibres.

3. *Level of Upper Third of Olivary Bodies.* The lowest of the tumors encroaches here on the floor and gray matter of medulla on the left side. The twelfth nerve and nuclei still can be seen, but the tenth nerve on the left side contains degenerated fibres and its nucleus is compressed and cells atrophied. There is a greater number of degenerated fibres in the left half of the interolivary tract, and at its ventral part is the same triangular patch of degenerated fibres. There are almost no raphe fibres running in from the left side. The left pyramidal tract is full of degenerated fibres; its nucleus is present on the left side.

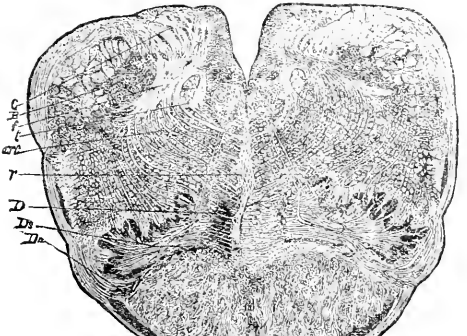

FIG. 2.—Case of Spitzka, Wood's "Reference Handbook," vol. viii., p. 166. The darkened area, D, in above cut shows the position of the degenerated area in our case, only it does not extend so far dorsally, and is somewhat smaller in extent.

[1] This shows no difference in the size of the two lobes. Nor would any be expected. The measurements were made, however, in view of the statement, afterward found to be incorrect, that the left eye was enucleated thirty years before death, during boyhood.—C. L. D.

The tumors had so infiltrated the pons and softened it that sections could not be made there.

From a study of the medulla it is seen that the left side tumors pressed upon the median lemniscus and caused in it a descending degeneration. This degeneration involved only its ventral part, but was diffused somewhat laterally. It extended down to the sensory decussation, but could not be well traced to the right or opposite nucleus of the column of Goll. The tumor also caused some degeneration by pressure on the left motor tract, and it injured and destroyed in part the nuclei of the left vagus, glossopharyngeal, and, probably, acoustic and fifth nerves.

Sections Made through the Anterior Corpora Quadrigemina.—The cells of the third nerve nucleus on the left side are few in number and atrophic. The nucleus on the right is normally distinct. The fibres from the posterior commissure are well defined on each side, also the descending root of fifth nerve. The fibres on the left side in the area of the lateral (lower) lemniscus seem less numerous and defined than on the right.

Microscopical Examination of the Optic Nerve and Tracts.—Sections were made through the optic decussation and at different points in the optic tracts on each side as far as their junction with the optic thalami and external geniculate bodies.

1. The sections in the decussation show a band of degenerated tissue crossing from the upper part of the left nerve to the lower part of the right tract.

2. Sections of the tracts show absolutely no degenerated fibres in the left tract, but a distinct band in the right, running superficially in its ventral part and apparently ending in the external geniculate body.[1]

Sections through the pulvinar of the optic thalamus show no distinct degenerative areas, though the right is less rich in fibres and cells than is the left side.

Summary.—Three tumors in floor of medulla, infiltrating and compressing and more or less destroying, left lemniscus, left pyramidal tract, left eighth, ninth, and tenth nuclei and nerves somewhat, left, and perhaps right, third nerve; probably fourth, sixth, and seventh nerves, but these parts could not be examined. Secondary degeneration downward of median part of lemniscus, and some degeneration upward of its lateral (lower) part. Some destruction of the ascending root of the ninth and tenth nerves. No positive change in occipital lobes. Degenerative strand from left optic nerve decussating completely into right optic tract and ending mostly in external geniculate body, partly in pulvinar.

Correlation of Symptoms to Lesions.—The oldest and most extensive process was on the left side. It began in the floor of the fourth ventricle at the level of the lower part of the pons. The first symptoms—vertigo and tinnitus—may have been due to irritation of the nuclei and deep fibres of origin of the vestibular and cochlear nerves (the bulbar vertigo described by Bastian).

The paræsthesia of the right side of the body was due to pressure upon and irritation of the sensory tracts (the lemniscus and formatio reticularis) by this left side tumor.

The hemiparesis of right side was due to the deeper infiltration of the tumors pressing on the left motor tract in the pons and medulla. There was more ataxia than pain, or anæsthesia or paralysis on the right side, and the examination showed the lemniscus (the tract for muscular sensations) to be involved.

The forced movements to the right were probably due to the involvement of the left middle cerebellar peduncle by the tumor.

The burning sensations in the right side of the face and the paresis of the left masseter and temporal were due to involvement of the fifth nerve. The dysphagia is explained by the disorganization of the ninth and tenth nerve nuclei.

[1] This corresponds with St. Bernheimer's description of the position of the crossed fibres. Neurolog. Centralbl., 1889.

The apparent total decussation of the optic nerve I [Noyes] can only explain by saying that even in man this does occasionally occur.

The decussating band of degenerated fibres appeared to go to the external geniculate body chiefly, and less to the pulvinar.

The ocular symptoms were due to involvement of, first, the sixth nerve on the right side, then of branches of third nerve to levator palpebræ,[1] then of both sixth nerves, then of irritation of fourth nerve, and of nuclei of third nerve to superior and inferior recti (rotatory and vertical nystagmus).

The ciliary muscle and iris were not involved. If there were, as the notes stated, early ptosis it would be in harmony with the arrangement of the third nerve nuclei as given by Hensen and Völckers, for there could not have been ptosis before involvement of the superior and inferior recti unless the nuclei of the levatores palpebrarum were situated more posteriorly than is stated in later tables.[2]

Wernicke has reported a case of tumor of the fourth ventricle in which there was this same order of phenomena, viz., first paralysis of the sixth nerve, and then ptosis, before other branches of the third were affected.

In a case of probable tumor of the fourth ventricle, reported by Barry and Bramwell, there was ptosis and paralysis of the superior and inferior recti, then of the internal recti.

Suckling has also reported a case of external ophthalmoplegia with ptosis, and paralysis of the superior and inferior recti, and right internus. This could be explained by Hensen and Völcker's arrangement, and by Starr's, but not by Kahler and Pick's.

Wernecke has reported a case of tumor of the fourth ventricle, with paralysis of the sixth nerve and ptosis, and this falls in with Hensen and Völcker's arrangement. It seems likely, at least, that the nucleus for the levator of the lid is a long one, perhaps overlapping the others.

The frequency of tumors of the brain-axis (pons medulla) is somewhat greater than is usually stated. They make up twelve per cent. of Putnam-Jacobi's collection of 649 cases, fourteen per cent. of Mills and Lloyd's 100 cases, and about the same proportion of Bernhardt's cases.

Apart from the value of our case as a contribution to the clinical history of tumors of the brain axis, it has some features of special interest. It shows apparently a total decussation of optic nerve-fibres. It shows certainly that the theory of the pinching of healthy fibres by a degenerated tract at a decussation does not cause degeneration in these healthy fibres, at the optic commissure at any rate. The course of the degenerated strand to the external geniculate body accords with V. Monakow's theory that the afferent tracts in the optic nerve-paths pass to this body, and that atrophy in the geniculate bodies follows enucleation of the eyes. The eye symptoms indicate perhaps a longer nucleus for the levator palpebræ than has been supposed.

The secondary degeneration downward of part of the lemniscus confirms the fact already established that this tract, though sensory, does degenerate a short way downward (cases of Spitzka, Homen, Meyer). The fact that the degeneration becomes gradually less as it descends, and does not certainly reach the nucleus of the column of Goll, shows that it is not rapid or complete, as happens when the degeneration follows the direction in which the tract carries impulses. It is more like such a degeneration as follows when one cuts off an axis cylinder process of a nerve-cell.

[1] The statement that there was early and marked ptosis is not trustworthy.

[2] Hensen and Volcker's arrangement of the ocular muscle nuclei is: Ciliary muscles, sphincter iridis, rectus internus, rectus superior, levator palpebræ, rectus inferior, obliquus inferior. Kahler and Pick's arrangement is: Ciliary muscle, sphincter iridis, lavator palpebræ, rect-internus, rect-superior, rect-inferior, obliquus inferior, obliquus superior (fourth). Starr's modification of this is: Sphincter iridis, ciliary muscle, levator palpebræ, rectus internus, rectus superior, rectus inferior, obliquus inferior.

TROPHO-NEUROTIC KERATITIS.[1]

By KENT K. WHEELOCK, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN FORT WAYNE COLLEGE OF MEDICINE.

My attention was first called to this class of cases some three years ago, while treating a case of herpes zoster ophthalmicus. The corneal ulcer in that case was central, and despite the ordinary cleansing solutions applied to the eye, hot fomentations, bandaging, etc., the ulcer extended in depth and circumference. Other conditions were also present, consequent upon irido-cyclitis plastica with hypopion, which it is not necessary to say more about. After the treatment usual in such cases had been followed a few days, the eyeball began to feel cold, as though it were a ball of ice. At this time I tested the corneal sensibility, and to my astonishment found that it was practically anæsthetic. I then applied one pole of the faradic battery to the base of the cranium and the other over the eyeball, and carried the strength of the current to the point of easy toleration and continued this for about fifteen minutes. After this use of the current the sensation of coldness passed away, and after the fourth application sensation returned to a large area of the cornea. Especially was this true of the lower segment of the cornea. My belief was then, and is now, that herpes zoster is a disease limited to the ganglionic nerve-enlargements in general, and in this especial case to the Gasserian ganglion in particular. My reasons for believing the lesion to lie in the Gasserian ganglion are based upon the general physiology of the spinal ganglia and upon the experimental physiological action of the Gasserian ganglion.

"The remarkable anatomical peculiarity of the posterior roots . . . is the presence of a ganglion. While we have no distinct idea of the function of these ganglia in connection with the transmission of impressions from the periphery to the centres, it has been shown that they have a remarkable influence upon the nutrition of the nerves after their division" (Flint).

According to Waller, when the roots are divided between the ganglion and the cord, the central end of the anterior root attached to the cord preserves its normal structure, while the peripheral end in a few days becomes degenerated; the tubes are filled with granular matter, etc., and, in short, undergoes those changes observed in all nerves separated from their centres. On the other hand, in the posterior roots the end attached to the cord undergoes degeneration, and the peripheral end—the one to which the ganglion is attached—preserves its normal histological character.

Bernard concluded from the above, and somewhat extended experiments, that the ganglia of the posterior roots have an influence over the nutrition of the sensitive nerves. Flint suggests that these points show the spinal ganglia to be trophic centres. It has been shown by Schiff that after division of the posterior roots beyond the ganglia the anterior roots contain altered fibres, which he believes to come from the posterior roots.

It is agreed, therefore, that the ganglia of the sensitive roots of the spinal nerves are the trophic centres of the sensitive spinal nerves, and that while traumatic herpes zoster produces phenomena essentially similar to the idiopathic, yet the lesion in the latter probably lies in the ganglia.

Since the observation of this case, and feeling that the pathology is practically located, I have made a practice of examining the corneal sensibility in all cases of corneal and conjunctival ulceration presenting certain definite characteristics. These characteristics may perhaps be better appreciated if the history of the cases is detailed.

CASE I.—Charles K——, a German, aged fifty-five, a machinist by trade, called upon his family physician to have his right eye examined as, he thought a piece of emery had gotten in it. The result of the examination, made by a very careful and competent man, revealed the fact that while there might be some foreign substance on the cornea, it had more the appearance of being sprinkled with fine sand or dust, and the case was referred to me.

At the first visit the complaint was of a feeling of sand in the eye. The pain was not much, and only of an occasional scratching. The eye was only irritable and the photophobia slight. The patient suffered very little conjunctival irritation compared with the extent of corneal lesion. Besides the appearance of sand on the cornea there was a grayish infiltration, shading off into perfectly clear corneal tissue at the peripheric areas.

I prescribed a two per cent. solution of boracic acid and a one per cent. solution of atropia, with the result of not improving the condition within twenty-four hours. At the second or third visit the notable absence of photophobia and lachrymation, as compared with the evident denudation of corneal epithelium, led me to test the corneal sensibility. I found it practically anæsthetic centrally, and this anæsthesia corresponded to the greatest corneal erosion. I then applied the Faradic current, as it was all I had at command, and after fifteen minutes the corneal sensibility was acute. Treatment was continued for some time. At each application the corneal anæsthesia passed away, but the restored sensibility would not remain till the next treatment. Strychnia was given, together with quinia, but the patient finally passed out of my hands. Tension was — 2 at least.

CASE II.—Kate S——, aged nineteen, large, well-made girl, farmer's daughter, and working at woman's work on a farm, consulted me December 9th of last year for a trouble of the left eye. The eye was somewhat irritable; little or no redness of the circumcorneal tissue, and no pain. There was a deep infiltration at the central part of the cornea, with a gray nebular infiltration shading off into clear tissue at the circumference of the cornea. The infiltrated area proper covered nearly one half of the cornea. My diagnosis was non-inflammatory interstitial keratitis, so miscalled, and I treated it for a few days as such. At a subsequent visit it was observed that the epithelium began to break down, leaving the appearance of an ordinary septic ulcer. Still there was no pain, and not only was there no redness but the sclerotic shone through the conjunctiva with abnormal clearness. A twisted spill of cotton brushed over the cornea showed absolute loss of sensation in central parts of the cornea, while it varied in degree as the clearer tissue was reached. The patient was immediately put upon strychnia and electricity. The electrical stimulation brought about immediate results by restoring sensibility where before it had been partially lost, and making the central parts of the cornea sensitive where before they had been insensible. The eye soon became irritable, blood-vessels ran from the conjunctiva up to the ulcer; the ulcer began to diminish in circumference and depth, and after over two months' treatment daily with electricity and strychnia, sensation has practically returned and the original ulcer area has only a thin, almost invisible nebulous superficial striation, with a small opacity at the centre, which is at present eroded before the use of the electrical current. After the use of the current for a period of fifteen minutes the cornea is clear, lustrous, and to the eye normal as to epithelial covering. At times, varying with the varying degrees of performance of physiological function of the fifth nerve, the photophobia, lachrymation, and pain become intense and last twelve or fifteen hours. At such times the corneal sensation is complete, and the case has to be treated as an ordinary septic ulcer.

CASE III.—J. A. H——, aged twenty-eight, telegraph operator, a strong well-made man, consulted me, March 12th of the present year. On March 7th was struck in left eye with a small twig of a dry weed while driving through a field. The pain was quite severe at the time, but passed away. Patient complained of a constant irritation, as though there were a foreign substance under the upper lid. Upon inspection cornea presented an irregular triangular area, with apex toward centre. The epithe-

[1] Read before the Fort Wayne Academy of Medicine, March 4, 1890.

lium was eroded and the border of area nebulous. A dossil of cotton brushed on cornea and conjunctiva corresponding to this wedge-shaped erosion showed marked loss of sensibility amounting almost to anæsthesia. The circumcorneal injection was slight. Faradic current markedly increased sensation, at same time restored lustre to cornea and made erosions invisible. Strychnia was also employed. Tension subnormal. This patient lived thirty miles away, and has been seen but once since first visit. No particular improvement was noticed.

As far as I am acquainted with the literature, this class of cases was first brought to notice by Dr. J. L. Minor, reporting them from the clinic of Professor H. D. Noyes, at the New York Eye and Ear Infirmary, and published in the *American Journal of the Medical Sciences* for July, 1881, under the caption "Anæsthesia of the Cornea," etc. In his smaller work, as well as in his recent larger one, Noyes classifies these cases as neuro-paralytic ulcers. This is manifestly incorrect, since many of these cases are not characterized by an ulcerative process in any respect, and never become so. The name neuro-paralytic ulcer should, in my opinion, be confined to those cases represented by gross brain-lesion, or where both the trophic and sensitive fibres of the fifth nerve are involved, so that we have facial hemianæsthesia as well as disturbances of the trophic fibres. Noyes claims a malarial origin for some of his cases and cured them with quinine, while others were not benefited by this drug. Those responding to quinine were associated with supraorbital neuralgia. None of my three cases presented this neuralgic element; in fact the cases were remarkable for the absence of all pain of a severe character. We are justified in naming the ganglion of Gasser as the seat of disease in this class of cases. According to Kölliker the sensitive fibres from the fifth nerve pass through the ganglion and do not unite with the ganglion cells. Landois thinks the unipolar cells give off fibres which supply the cornea through the ciliary nerves. Magendie observed that intracranial section of the fifth nerve resulted in inflammation and necrosis of the cornea and subsequent loss of the eye. The trophic fibres seem to come from the most internal portion of the ganglion, and when section is made through the ganglion, so as to include these fibres, there is loss of sensation with subsequent ulceration. The prognosis in these cases is good, provided the element of time be regarded as a therapeutical agent. Cases of malarial origin offer the most flattering results.

Treatment must necessarily look to restoration of function of the nerve, and this is best accomplished through the stimulating influence of the constant current supplemented by strychnia. The iodides and mercurials may do good in certain cases. As to local treatment the bandage will do good by restraining the motility of the eyeball, and thus preserve the new epithelial tissue developed in process of repair, and further in preventing multiplication of septic germs which might otherwise find a lodging-place in the broken tissue. Hot-water compresses assist in stimulating the growth of epithelial cells, while antiseptic solutions may appeal to our religious aspirations to approach holiness.

Mechanism of Respiration in the New-born.—Dohen, from a study of this subject at the clinic of Königsberg, reaches the following conclusions: 1. The respiration of the new-born is thoracic. 2. The elevation of the thorax begins at the summit and descends progressively. 3. The tidal air averages 35 c.c., and reaches a maximum of 120 c.c. 4. The exchange of air is feeble in the first days after birth; at the end of the first week is a third larger than the first day. 5. Generally at the first inspiration the lungs are not filled with air, the alveoli unfolding only on the second day (a fact of medico legal importance). 6. The respiratory curves of the new-born present no stationary points.—*The Brooklyn Medical Journal.*

URINE WITH HIGH SPECIFIC GRAVITY.[1]

By J. H. LINSLEY, M.D.,

NEW YORK.

ELLEN B——, Irish; single; aged twenty-five. Her mother died of heart disease; the father, three brothers, and one sister, of phthisis. The patient herself has always enjoyed good health.

February 23, 1890.—Her present illness began two weeks ago. She complains of headache, anorexia, dulness, and general malaise. There has been no well-marked chill; temperature, 101.5°, pulse, 112, respiration, 20. Physical examination of the chest and abdomen is negative. The patient was sent to bed, and ordered a cathartic dose of sulphate of magnesium.

February 24th.—Temperature, A.M., 102°; pulse, 112; temperature, P.M., 102.8°; pulse, 116.

February 25th.—Temperature, A.M., 103°; pulse, 120; temperature, P.M., 103.8°; pulse, 120. At 8 P.M. she was given phenacetin, gr. x. At 10 P.M., temperature, 99.8°; pulse, 100.

February 26th.—Temperature, A.M., 103°; P.M., 103.8°; pulse, 120.

February 27th.—Temperature, A.M., 103.4°; P.M., 104.5°; pulse, 120.

February 28th.—Temperature, A.M., 104.3°; P.M., 104.2°; pulse, 116. On this date the urine was examined; specific gravity, 1050; reaction, acid; color, reddish yellow; odor, fetid; consistence, limpid. It was cloudy, and had a white or slightly flesh-colored precipitate. The quantity of urea was .0033 grm. per cubic centimetre, or 3.3 per cent. The chlorides were diminished; while the phosphates were enormously increased. Microscopical examination showed pavement epithelium, uric acid, amorphous phosphates, and the ordinary bacteria.

The interest in the case centres upon the high specific gravity, with the proportionately small amount of urea. Supposing the quantity of urine voided to have been 1,500 c.c., the quantity of urea would have been 49 grammes, the normal quantity being thirty to forty grammes for the twenty-four hours. The exact quantity of urine was not known, although considerably below the normal.

Another curious fact was the presence in the same precipitate of uric acid and amorphous phosphates. The excess of phosphates (which formed the precipitate) could be cleared up by adding a few drops of nitric acid; while upon the addition to the urine of a small quantity of liquor potassæ or ammonium hydrate, an enormous quantity of phosphates was precipitated. I have not had time to consult the literature on the subject to determine the rarity of this case; but in three thousand consecutive examinations of urine, I have never seen any such condition as this, and on consulting with several of our pathologists, I have ascertained that, in their experience, no such specific gravity has been reached in urine free from sugar. The specific gravity was not only taken with a urinometer carefully tested and corrected, but also with a Mohr-Westphal balance at 15° C.

Since February 28th (the date on which the urine was examined), up to the present time, her temperature has ranged from 100° to 104°, and the pulse has always been above 100. She has had no eruption on the abdomen, and no marked symptoms of typhoid; in fact, an examination of all the organs was negative. The specific gravity of the urine has not fallen as yet below 1030 in any one specimen examined, and an excess of phosphates has continued.

41 EAST TWENTY-FIRST STREET, March 12, 1890.

Asitia is a word employed to denote abstinence from food. It has recently come into frequent use in accounts of Succi, the Italian fasting man, who lately exhibited himself in London.

[1] Reported to the New York Pathological Society, March 12, 1890.

Clinical Department.

FRACTURES OF THE MAXILLARY BONES.

By WILLIAM F. EDGAR, M.D.,

LOS ANGELES, CAL.

THE following case occurred some twenty years ago, but has never before been reported:

I. S— , a hardy middle-aged frontiersman and bear-hunter, went, on or about March 17, 1871, out in the Tejon Mountains, in Southern California, in pursuit of bears, and having reached the desired locality, dismounted, tied his horse, and started off, rifle in hand, on a narrow path or trail through the brush, but within a hundred yards or so, suddenly met, face to face, a large grizzly. So close together did they come, indeed, he said, that he did not have time to take deliberate aim but threw the muzzle of his rifle, as quickly as he could, against the body of the bear and fired. The shot did not kill the bear outright but only caused him to "bat his eyes (blink) and stagger," but he immediately raised upon his hind feet and struck the hunter with the right paw, raking him from left to right, across the chest, tearing the flesh so as to expose some of the ribs and part of the sternum and bringing him down, when the beast took his face in his mouth, lacerating the flesh and crushing the lower jaw, then he let go his hold of the face and the hunter managed to turn face downward. Then the bear bit him in the back, with less damage, however, but in doing so tore off a piece of the hunter's coat, which hung to one of his tusks and this frightened him away. The hunter did not lose his presence of mind, and as soon as he felt assured that his enemy had left him, he raised himself upon a stone near by, where he sat a few minutes and then reached his rifle which was near, and by its aid, raised himself to his feet, and bleeding and hatless, started back on the trail for his horse, and on reaching a point some seventy-five or eighty yards from the place of encounter, he came upon the dead body of the bear. After reaching his horse he said that he came near giving up in despair, as his horse would not permit him to mount, not recognizing him, as he was bloody and could not speak. He, however, finally succeeded in mounting without the rifle and struck for camp, some three miles distant, where he arrived after dark, when his companions put him into a common road wagon and started over a rough mountain road for Los Angeles, about one hundred miles distant. They travelled all that night, all next day, and until ten o'clock at night of that day, when they reached the Sisters' Hospital of this city and I and the late Dr. N. P. Richardson were summoned to his assistance.

We found the patient very much exhausted, as he had been about thirty hours without food, water, or sleep, and the inferior maxilla fractured in three places, besides terrible lacerations of the flesh. On the left side near the ramus there was an oblique fracture, and on the same side, just in front of the mental foramen another fracture, transverse, and on the right side a transverse fracture, between the second bicuspid and first molar tooth.

Opposite each fracture there was a deep laceration of the soft parts, the effect of the animal's tusks. At the fracture near the ramus on the left side, the flesh and beard had been pushed into the mouth, inverted like the finger of a glove, and the first thing done toward repair was the restoration of the soft parts in this locality as far as possible, and then we commenced to adjust and secure the fragments of broken bones with silver wire twisted around adjacent teeth as the best temporary means, at least, in view of the exhausted condition of the patient, and after administering such stimulating and nourishing fluids as was necessary, applied the usual support to the jaw and left him till the following morning (Sunday) when we found that the contractions of the digastric, mylo-hyoid, genio-hyoid, and other muscles connecting the front and central fragment of bone with the os-hyoides had drawn the teeth, which were small and rather conical, out of the wire loops and that the patient was but little if any better off than when we first saw him. We then got a dentist to make a thin malleable silver plate, perforated with holes opposite the teeth, and this was applied and secured to the fragments with silver wire, and with some feeling of encouragement that we had a retaining apparatus and with the usual external support to the jaw, we left the patient till evening.

At our evening visit we became very much dissatisfied with our apparatus but concluded to risk it till the next morning (Monday), when we might be able to call in some dental assistance if needed. At our morning visit we found the pale and fractured bones again nearly disconnected, and concluded that drilling and wiring the fragments together was the only and last resort that offered the patient any chance for recovery, and we called in two of the principal dentists in the place, Drs. French and Crawford, and after sufficient consultation Dr. Crawford, upon solicitation, drilled a hole through the end of each fragment of bone just below the line of the bottom of the alveolar processes and put a small silver wire through each hole and drew them together on the outside, and after proper adjustment and coaptation, twisted them firmly together. At the fracture on the left side, near the foramen, the first bicuspid had to be drawn, as a proper adjustment could not be made there in consequence of the loss of a small wedge-shaped piece of the bone, leaving a small notch at the root of the tooth. After the adjustment of the splint and external support of the jaw, it was found that the opening made by the drawing of the bicuspid tooth, together with the smallness of the corresponding tooth in the superior maxilla, was just what was needed, as through it nutritive fluids were taken in freely, at first by inserting the small end of a funnel into it but as the quantity was sometimes greater than the patient desired, a small piece of soft rubber tube a foot long was adjusted to the end of the funnel, which being inserted into the mouth instead of the end of the funnel and being grasped between the thumb and forefinger of the patient, the quantity he desired to swallow at once was perfectly regulated. No anæsthetic was given the patient during any of these operations and he complained very little. Between two and three weeks the external support to the jaw was removed and the patient could talk very well, and between three and five weeks the wires were gradually removed and at about the end of eight weeks he left the hospital with a good jaw. The scars were soon hidden by the growing beard, and the best evidence that his personal appearance was not seriously marred was that he got married a few months after leaving the hospital.

Progress of Medical Science.

Acute Œdema Glottidis after Potassium Iodide.—Cases of this nature are few in number, and one reported by Dr. Groenouw may be quoted. A strong, healthy man, forty-three years of age, suffering from optic atrophy, and with the urine quite free from albumin and sugar, was treated with the iodide of potassium in the form of a watery solution, in doses of seven to fifteen grains thrice daily. On the afternoon of the second day, when he had taken about forty grains of salt, he complained of a feeling of rawness, with pain on swallowing, localized in the right side of the larynx. These symptoms, which were not by any means prominent, were not more pronounced on the evening of the sixth day, after the use of a little over three drachms of iodide. The same night, after two hours quiet sleep, the patient awoke, began to cough, and noticed suddenly that although the expiration was free, the inspiration was difficult, and he felt as if a valve were in the throat. The difficulty lessened in the space of two hours, and he slept again, the dyspnœa having quite disappeared by next morning. In the after-

noon, on examination, the right ventricular band was œdematous, as also the mucous membrane over the arytenoid cartilage and the ary-epiglottic ligament. After an intermission of two days, the iodide was resumed; and although the dose was a full one, no further symptoms of iodism appeared. In spite of the severity of the attack tolerance was established. The iodide of potassium given was exactly the same as other patients were using, and it is not likely that the symptoms were due to impurity of the drug. Groenouw observed a similar case two years ago in a woman sixty-six years of age, who was the subject of a moderately enlarged thyroid, but without difficulty of breathing, and was suffering from oculomotor palsy of one eye, for which iodide of potassium was prescribed in small doses. After seven grains, severe coryza and conjunctivitis, with great dyspnœa and loss of voice, came on. Examinations showed marked pharyngeal catarrh and evident swelling and redness of the ventricular bands. Three days later, when the symptoms subsided, four grains were given daily for three days; but on being increased to twice daily there appeared—more or less every time—hoarseness, difficulty of swallowing, and pain in the head. The drug was accordingly stopped for four days, and then the patient took about four grains daily, diluted with much water, the dose being gradually increased in the course of the next two weeks to fifteen grains a day. On attaining this amount, it had to be reduced on account of pain in the throat and general restlessness; and seven days later it was discontinued altogether. Groenouw thinks the following conclusions may be drawn: After the administration of iodide of potassium, there occurs in certain rare cases great dyspnœa due to œdema of the glottis, sometimes so extreme as to demand rapid tracheotomy. It does not arise from long use or large doses—relatively small amounts have hitherto induced it; and other symptoms of iodism, such as headache, are wanting. The action is local upon the larynx, not part of a general œdema. Its cause is certainly the iodide, not the potassium, and it cannot be ascribed to any impurity. No local or general diseased state, for instance, cardiac or renal disease, can be recognized; and the cause must be looked for rather in an idiosyncrasy of the individual, although even this is not by any means absolute, as a complete tolerance may be established after a few days pause.—*The Practitioner*, June, 1890.

Recent Remedies Employed in Pertussis.—Dr. Stepp has published a second article on the treatment of whooping-cough with bromoform. In one hundred cases treated there was not a single failure. He gives the bromoform pure in one-drop doses in a teaspoonful of water. On account of its high specific gravity the bromoform sinks to the bottom of the spoon, and there forms an isolated drop. The teaspoon should then be carried well back into the mouth, and its contents rapidly swallowed. The dose, given three or four times daily, varies as follows: For children of three to four weeks, one drop; in older, nursing children, three drops, according to the intensity of the attack; in children of two to four years of age, four or five drops; up to seven years of age, six to seven drops. Dr. Stepp claims diminution of vomiting, shortening of attacks, and increased appetite, with a perfect cure in from two to three weeks. But a small quantity of bromoform should be ordered at a time, as it is volatile. Protect it from the light to prevent decomposition. Red bromoform should be rejected, as it is decomposed and contains free bromine, and is consequently unsuited for administration. Dr. Rothe warmly recommends, for children of from one to two years of age, iodo-phenol in whooping-cough, administered after the following method: Phenic acid, 1 gramme; alcohol, 1 gramme; tincture of iodine, 10 drops; tincture of belladonna, 2 grammes; peppermint water, 50 grammes; syrup of white poppies, 10 grammes. Mix. One teaspoonful for a dose. Older children in proportion. Hydrate of turpentine is also favorably mentioned. It forms large, colorless, odorless, rhombic crystals with a weak aromatic taste, and easily soluble in hot water. Lepine first recommended it in 1885 as having a similar action to oil of turpentine, without the unpleasant effects. In small doses (three to nine grains) it acted on the bronchial mucous membrane, and was found useful in chronic catarrh. In large doses, it diminished secretion, and was given with excellent results in bronchorrhœa. When the kidneys were healthy, no evil result followed; but when those organs were diseased, large doses produced hæmaturia and albuminuria. Later, Germain Sée, who gave large doses to animals without harm, and to man as much as thirty grains daily in alcoholic solution as pill, praised the good effects of the hydrate in the initial catarrh of phthisis, where it lessened secretion; and he recommended it as a hæmostatic in bleeding from the lungs. In this opinion he has been confirmed by Lazarus. Recently Manasse has made careful trials of it in forty-one cases of pertussis. To children under a year, daily doses of over twenty grains were given without ill effects upon the renal or digestive organs. In none of the urines of older children examined, after amounts of thirty-five to forty-five grains daily, was albumin or blood found. The ages of the patients ranged from nine months to twelve years. The general result was, that after four to five days' use of turpentine hydrate (twenty to forty-five grains, according to the age of the child), there was lessening of the attacks—at all events they became much mitigated. In all the cases there was bronchial catarrh, which improved more rapidly than usual and soon entirely disappeared.

Oil of Turpentine Treated with Potassium Hydroxide in Catarrhal Affections of the Air-passages. — Dr. Kogelmann had repeatedly tried inhalations of the vapor of ethereal oils, especially oil of turpentine, in commencing catarrh of the nasal cavities, but always without effect, the cold taking its course. In December last, having taken cold in an evening walk in cloudy, damp weather, he tried an inhalation of the vapor of oil of turpentine treated with potassium hydroxide, with surprisingly good results. He had mixed in a flask for some chemical work nine volumes of rectified oil of turpentine, one volume of ordinary petroleum, and one volume of an alcoholic solution of potassium hydroxide (one pint by weight of caustic potash in five pints by weight of absolute alcohol). The mixture was well shaken and allowed to settle. It was inhaled, the nose being held close to the mouth of the flask, for five long breaths, every quarter of an hour. After five or six repetitions the cold was completely relieved. As a matter of precaution, the inhalation was repeated on the three following days. Whether the presence of petroleum is useful, or whether it is necessary to use so concentrated a solution of potash, or whether, as is very probable, the sodium hydroxide would act as well, he has not determined. Oil of turpentine treated in this manner is free from any trace of acid formed by oxidation, and possibly in this consists its advantage over ordinary turpentine. Lastly, it may be mentioned that this mixture had been standing, for about fourteen days before it was used, in a half-filled flask, but never exposed to direct sunlight.—*London Medical Recorder.*

Temporary Stammering Caused by Tonsillitis.—Dr. H. Rainsford reports in the *British Medical Journal*, of May 3, 1890, the case of a young woman who consulted him on account of a subacute tonsillitis with slight febrile symptoms; she could not then speak a word without stuttering badly. When she was convalescent, she asked me if the stammering would cease when her throat was well, for she said that she could speak as well as anyone before the quinsy came on. A favorable prognosis was given, and after a week on bromide she could speak almost as well as ever. The author thinks the case a rare one, and asks whether the stammering was not due to loss of power of co-ordination of laryngeal muscles from reflex causes. There was no alteration in the sound of the voice, indicating that the larynx was free from inflammation.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 26, 1890.

COWS' MILK AND TUBERCULOSIS.

WE have repeatedly had occasion to point out the possibility, nay, probability, of spreading consumption through the agency of the flesh and milk of tuberculous cattle. There is no good reason why the various Boards of Health should not devise practical measures for the abatement of the grave menace to the health of an unenlightened and unsuspecting community implied in the continued sale of disease-tainted flesh and milk. There is enough evidence at hand now to warrant energetic interference.

In the *New York Times* of recent date we find a timely exposition of this subject, under the suggestive title of "Advice and Warning." The article refers to a letter published in Hartford by a well-known veterinarian. In that letter there was given the history of one herd of cattle numbering two hundred and forty animals, fifty per cent. of which died of tuberculosis in two years.

"Certainly a startling fact, and it becomes still more so when we consider that the milk from the sick and dying cattle was daily peddled to customers in North and South Norwalk." New legislation was urgently needed, this veterinarian declared, for the protection of the people. "The question involves in a vital way one of our chief food products. Milk is sold from tuberculous cattle, and such cattle are killed and sold as beef every day. The offspring of such cattle are sold to the sausage-manufacturer, and even the older and sick animals themselves. Should not the laws protect us from such ignorance or cupidity?"

The *Times* says that since the publication of Dr. Gardner's letter "the Connecticut Commissioners on the Diseases of Domesticated Animals—Messrs. E. H. Hyde, T. S. Gold, and J. W. Alsop—have published a circular of warning and advice, addressed to the owners of cattle. This action deserves attention in this city, because a part of our milk supply is brought from Connecticut. Moreover, it is an indication of the interest now beginning to be shown by public officers everywhere in a question of the gravest importance—interest that will eventually cause the enactment of salutary laws to prevent the poisoning of the people by dairymen and butchers who are ignorant or dishonest. The Commissioners say, at the beginning of their circular, that the discoveries of modern science have so important a bearing upon the public health that the well-established facts in regard to tuberculosis, commonly called consumption, should be disseminated as widely as possible. Some of the statements and instructions of the Commissioners may be found below:

"The facts are well settled, not only that tuberculosis is a communicable disease, but also that it occurs in many animals—especially in the human and bovine races—and is intercommunicable between them. The time is coming when some strict sanitary rules will be adopted in all cases of human tuberculosis. The necessity for this is generally admitted. The time has already come for the stock-owner to exercise watchful care over the health of his herds. The soundness of all purchased animals should be carefully investigated, as well as their antecedents. A consumptive person should never have charge of cattle. An attendant may contract the disease from them or give it to them. The flesh of tuberculous animals is dangerous as food; hence there is no use in trying to fatten them for beef. In milch cows, in addition to the common danger of contagion, the milk is unsafe for food, even for swine or poultry, and it only remains for the owner of a tuberculous subject to meet the loss promptly and slaughter the animal before others contract the disease.

"We do not wish to appear as alarmists, and create any unnecessary excitement among farmers or consumers of any products, yet we deem it prudent to exercise caution and be on the safe side, where also lies true economy, and would advise that all animals that are thriftless and show the symptoms of tuberculosis be destroyed, though the disease may not have progressed to the degree of rendering the animal apparently worthless.

"The prevention of the spread of tuberculosis and the eradication of the existing cases depend upon the cattle-owners themselves, and on them rests the responsibility, which is grave indeed, as so vitally affecting the welfare of both man and beast. Therefore this commission does not consider that the State should exercise the same authority over tuberculosis as in the case of contagious pleuro-pneumonia and slaughter infected or suspected animals at the public expense. Yet the Commissioners consider it their duty to investigate all cases of suspected contagious disease, to control the same, as far as possible, by advice and authority, for the preservation of the public health, as well as the material interests of agriculture, and in accordance with these views issue this notice of warning and advice."

We cannot do better than reproduce the comment of the *Times* on the whole subject, which is to this effect:

"But if the danger be so great why should not the State take action for the protection of consumers who are exposed to it? If it be expedient for the State to prevent by legislation and inspection the sale of milk that has been adulterated with water, ought not the sale of milk that carries the germs of consumption to be prevented in like manner? Must the people be content with such action as owners of herds may take in response to a circular of advice and warning? The admissions of the Connecticut Commissioners concerning the danger of infection are so important that a recommendation for the exercise of the State's police power should accompany them. But if they will continue to issue circulars of this kind some good will be accomplished, for such warnings

tend to make the people familiar with the facts, and a general dissemination of these will surely cause the enactment of such laws as are needed."

THE PAYMENT OF TRAINED NURSES.

An active controversy has been going on in the columns of the *New York Medical Journal* as to whether trained nurses should receive wages while in course of training. The profession of nursing is one of those rare and fortunate ones wherein the pupil gets very well paid for the work which she does in getting the education that afterward secures for her a very remunerative means of livelihood. Dr. J. West Roosevelt maintains, if we understand his position, that hospitals ought not to pay the trained nurses any more than the laws of supply and demand compel them to do in order to get good material for their classes and for the care of the wards. In other words, the same principle should be applied here that is applied to the medical staff of dispensaries and hospitals. The young medical men do work here which is severe and trying, and involves special knowledge and skill, but they are not paid, because hospital managers know that good hospital internes can be got for nothing.

It is perhaps a question whether a good quality of nurses can be obtained without paying them, and Mr. Ludlam, a superintendent of one of the hospitals of the city, seems to favor a continuance of the present plan. But the application of strict business principles ought, we think, to apply to all departments of hospital management; and if good nurses can be obtained for nothing, the hospital authorities have no right, on sentimental grounds, to pay salaries when salaries are not necessary. If sentimentalism is allowed to rule in the management, however, the house physicians are entitled to their share.

INSANITY PROCEEDING FROM THE COLON.

Few general practitioners will agree with the eye-specialist who stated that he had rejected as mere superstition the prevalent views concerning the importance of securing thorough action of the bowels in sickness. While it is true that some persons are much more affected by the occurrence of constipation than others, it is also true that the health of a large part of the human race is greatly influenced by the state of the intestinal functions. As someone has expressed it, one of the best preparations for active life is a good set of bowels. Probably the worst indictment that can be brought against our modern system of education is that it cultivates in the boys and girls a habit of intestinal sluggishness—by compelling them to hurry off in the morning to school, and to repress the desire for stool—by producing feebleness of muscle and passive congestion of pelvic organs as the result of long sitting and want of physical exercise. This habit is, in men, sometimes corrected by the out-door labors of after-life; but in women, especially those of the wealthier classes, it is confirmed by confinement indoors and want of muscular exercise. The important part which intestinal inactivity (glandular as well as muscular) bears in the causation of sickness is witnessed by the fact that purgatives are among the remedies most frequently taken. Probably no other class of drugs is so often called for.

It will be readily admitted that many of the milder affections of the nervous system may be caused by excessive and long-continued accumulation of fæces in the large intestine, or rather by the abnormal state of the system which permits or arises from such an accumulation. Since the discovery of the nature and poisonous influences of ptomaïnes, and kindred bodies, and of their formation in certain abnormal conditions of the digestive tract, the dangers of accumulation of fecal matters in the large intestine have been more generally understood. That insanity could be due to such a cause could not be admitted without direct proof.

In the *Alienist and Neurologist*, January, 1890, Dr. Moyer relates three cases in which grave mental disturbance seemed to be due to disorder of the colon, with accumulation of fæces in it, and was cured by emptying of this organ.

In the first case, a married woman, without inherited or acquired neurotic tendency, and in every way healthy, had, eighteen months before, begun to suffer from obstinate constipation, loss of appetite, general debility, and loss of flesh. At the end of six months occasional attacks of fainting were observed, the attacks beginning with pain in the left hypochondrium and a sense of suffocation. During the last six months the attacks became more frequent, and were attended by vomiting. There was tenderness in the region mentioned, but there was no fever. The patient gradually developed marked symptoms of insanity, restlessness, sleeplessness, incoherence, confusional hallucinations, and non-systematic delusions of a depressed and melancholic character. Upon examination there was found great wasting of muscles and fatty tissues, contraction of flexor tendons of the thigh, weakness and irregularity of the pulse. The skin was dirty-brown, and covered with branny scales. The eyes, heart, lungs, kidneys, and sexual organs seemed normal after careful examination. There was no fever. The mental symptoms were as described. Upon the abdomen a line of superficial dulness extended transversely across on a level with the umbilicus, and in the left inguinal region a lobulated mass could be felt, indistinctly outlined. A copious rectal injection of water, containing two ounces of listerine and one drachm of common salt to the pint, was given by means of a tube, passed well beyond the sigmoid flexure. Upon removal of the tube it was found to be coated at the end with dark, waxy, adhesive fecal matter, unlike that which had been washed away. After ten daily injections, which brought away each time portions of this hardened mass, the bowels had begun to move easily, the mind had become clear, the appetite had greatly improved, and the patient had, in every way, entered upon convalescence.

In the second case, a constipated, debilitated, panophobic melancholic, with suicidal tendencies, who had refused food for months, and had required artificial feeding, was treated with a large injection, which relieved him of an immense quantity of stored-up fæces. He ran away, and shortly afterward wrote an intelligent letter for his clothing.

A third case is related in which a young man, of neurotic tendency, who had become morose, suspicious, and quarrelsome, was completely restored to health by a

rectal injection which brought away a large mass of dark, tarry, offensive fæces.

Two important suggestions are made: that accumulation of fæces is not disproved by the occurrence of free passages, and that treatment should be by large, repeated, high injections, purgatives doing only harm.

GONOCOCCI IN NON-SPECIFIC URETHRITIS.

Professor Straus has recently recorded an instance of gonococci detected in the urethral discharge from a youth aged sixteen, who had never had sexual relations with any woman, but who was addicted to masturbation from the age of twelve. Two days after indulging this habit to an unusual extent severe pain during micturition ensued. It was followed by well-marked symptoms of blennorrhagia. The discharge contained gonococci absolutely similar to those found in the pus of a patient suffering from ordinary blennorrhagia. According to the *British Medical Journal* this case would show that Neisser's gonococcus may exist as a simple saprophyte, and that by means of slight irritation it may invade the epithelium and determine characteristic catarrh.

It will be remembered that, several years ago, Dr. E. C. Wendt reported the occurrence in the scrapings of healthy male urethras of microbes in all respects similar to true gonococci.

The final proof of the identity of these organisms with Neisser's micrococci, by the inoculation of pure cultures, is wanting both in the observations of Dr. Wendt and Professor Straus.

News of the Week.

The First Case of Extirpation of the Seminal Vesicles.—Dr. E. Ullmann, of Vienna, reports in the *Centralblatt für Chirurgie*, the first case of extirpation of the seminal vesicles. In a boy, aged seventeen years, castration was performed on the right side owing to tuberculosis of the epididymis, and a considerable swelling and solidity of the right vesicula seminalis was noticed at that time. Two months later extirpation of the vesiculæ seminales was performed in Professor Albert's clinic. Starting from the perineum, the anterior wall of the rectum was detached; both the vesiculæ seminales and the right vas deferens were removed. Perfect recovery followed. Dr. Ullmann recommends this operation in primary tuberculosis of the epididymis when the epididymis of the other side is healthy, and the vesiculæ seminales tuberculous; also in primary tuberculosis of the vesiculæ seminales.—*British Medical Journal.*

Treatment of Goitre.—Professor Mosetig von Moorhof, of Vienna, recommends injections of iodoform (iodoform, 1; ether, 5; olive-oil, 9; or iodoform, 1; ether and oil of olives, of each, 7 parts) in parenchymatous goitre. When from 1 to 2 grammes of this mixture are injected from five to ten times at intervals of three or four days, a decrease in the size of the neck of from two to four centimetres invariably occurred in 79 cases so treated. In substernal goitres it is sufficient to make the injections into the suprasternal part. The advantages of this method, as compared with parenchymatous injections of iodine, are that inflammatory complications never occur. Suppuration has never been observed in Professor Moorhof's cases.

A Curious Delusion.—A Birmingham man, while under the influence of drink, knocked off his great toe with a hammer, imagining that he was cutting his throat with a carving-knife.

Death from Nitrous Oxide.—The first death in Canada under nitrous oxide is reported from Montreal. A man, aged twenty-four, went to the office of a dentist to have a tooth extracted, and requested to have nitrous oxide administered. After assuring himself that the patient was not suffering from heart or lung disease, the dentist administered the gas. No sooner had the tooth been extracted than the patient gave a gasp and fell over in the chair. He was placed upon the floor and artificial respiration performed, but without restoring animation. The patient was not under the influence of liquor, and five hours had elapsed since last taking food (breakfast). The purity of the nitrous oxide was tested shortly after the accident by the President of the Dental Association, Dr. Beers, who himself inhaled it from the same inhaler. The verdict of the jury was that the man died from syncope, caused by the administration of the gas, and they exonerated the dentist from blame.

"**A Specialist,**" says Dr. Collins, of London, "without general knowledge, realizes the ideal of the grammarian who, on his death-bed, lamented that, instead of dissipating his energy over the whole of etymology, he had not restricted his studies to the accusative case."

The Contagiousness of Leprosy.—Dr. Hansen, the well-known leprosy expert, is fully persuaded of the contagiousness of leprosy, and of the efficacy of hygiene and isolation for its suppression. He attributes the immunity of the Norwegians in America to their adoption of habits of greater cleanliness and their improved social state. That there are instances of contagion, well authenticated, is an absolute fact; even Boeck, anti-contagionist as he was, met with such an instance when in America. But there are conditions and limits to the contagion; probably it occurs only through inoculation, and, like syphilis, it may be transmitted from parent to child, as well as by personal intercourse in later life.

The Epsom Medical College, says the London correspondent of *The Occidental Medical Times*, is an institution unique in its way. It gives home and pensions to a number of members of the medical profession who have failed in the battle of life; but its most important work is the maintenance of a first-class boys' school. It is, in fact, a public school, with a medical foundation—*i.e.*, there are a number of scholarships for the sons of medical men who are educated for a nominal sum, just as at Eton and many other of the great public schools, there are "foundation scholarships." The vast majority of the boys, however, pay the full usual fees, and the parents of many of them belong to other professions than medicine. On leaving school, a considerable proportion of the boys have recently been successful in obtaining scholarships at Oxford, Cambridge, and the London Medical Schools.

Mississippi Valley Medical Association.—Dr. Frank Woodbury, of Philadelphia, will read a paper, and Dr. John A. Wyeth, of New York, has consented to deliver the address before the Mississippi Valley Medical Association at its annual meeting in Louisville, October 8, 1890. Quite a number of prominent medical men in the Mississippi Valley have given in titles of papers to be read, and promised to attend and take part in discussions. A large and profitable meeting is already assured.

The Alvarenga Prize of the College of Physicians of Philadelphia, consisting of one year's income of the bequest of the late Señor Alvarenga, of Lisbon, has been awarded to Dr. R. W. Philip, of the Victoria Dispensary for Consumption and Diseases of the Chest, Edinburgh, for his Essay on Pulmonary Tuberculosis, which will be published by the College.

A Curious Malformation of the Female Urethra.—Dr. D. Tod Gilliam, of Columbus, O., writes: "In your issue of July 12th, Dr. Alexander W. Stein gives a schematic drawing of a congenital malformation of the urethra in a male which tallies so perfectly with one I discovered a few months since in a female, that I feel it my duty to place it on record. The patient, aged about twenty-six, was taken with strangury and retention of urine, and her sufferings were so intense that I was sent for. Being occupied, I sent my son, who is quite expert in the use of the catheter, and upon his return I was much surprised to learn that he had failed to relieve the patient. I immediately repaired to the house, and although the urethra seemed patulous, I also failed to reach the bladder. I now administered chloroform, and upon digital examination found at the posterior third of the urethra a condition identical with that figured in the cut above mentioned. The apposed surfaces, however, seemed to be adherent, and separated with a sensation similar to that of a recently united incised wound. Bloody urine followed the withdrawal of the finger. As the woman was a mistress and her liege was suspected of having administered cantharides, I attributed the dysuria to the latter, but not the malformation."

Registration without Examination.—By a recent decision in Harrisburg, Pa., the physicians of Pennsylvania who have practised three years under the law are entitled to registration as apothecaries without examination.

A Young Smoker.—There is a child in Trenton, N. J., four years of age, who has smoked tobacco since he was seven months of age. He is quoted as a remarkable instance of hereditary taint, and was weaned early by the proud mother in order that he might give full bent to his taste. A little daily counter-irritation in the shape of spanking might turn the thoughts of this youthful monster in another and better direction.

The New Jersey Medical Law Bad for Hotel Practitioners.—Many New York and Pennsylvania doctors are indignant over the Medical Examination Law of this State, which went into effect on July 4th. The law, unless on a test case it be found unconstitutional, will prevent doctors from outside of New Jersey from practising at the summer resorts of the State. It requires that every physician seeking to practise within the limits of New Jersey after its passage must submit to a formal examination by State officers. The following exemptions only are made: "Commissioned surgeons of the United States army, navy, or marine hospital service, or regularly licensed physicians or surgeons actually called from other States or Territories to attend cases in New Jersey." Physicians called in consultation or summoned to attend special cases were thus relieved of the necessity of passing an examination. All others, however, including the hundreds from New York who reside in the big hotels or cottages at the sea-shore, or inland towns of Jersey, during the summer, or own their own homes there, are precluded from practising in the State. Even in case of an urgent sick call a New York physician would, it is thought, violate the law if he prescribed medicine or gave advice in the case, unless he had been examined by the local authorities. Practice in violation of the law is punishable by a fine of $50 to $100, or imprisonment for ten to ninety days, or both.

A Hospital for Consumptives.—Steps are being taken by many prominent citizens of Philadelphia to found a hospital for consumptives in that city.

Are People Buried Alive?—A sensational item is going the rounds of the daily press to the effect that physicians are convinced that many persons are annually buried alive. Nonsense! Where are your facts, gentlemen?

Privileged Testimony.—A physician who, contrary to all law and gospel, recently gave his testimony in a suit for divorce, charging his patient, the wife, with unchastity, was very properly rebuked by the judge, and his testimony promptly ruled out.

Death of Dr. James H. Patterson.—Dr. James H. Patterson, the County Clerk of Monmouth County, N. J., died at midnight Friday, at his home, in Shrewsbury, aged fifty-three. Dr. Patterson was one of the best known physicians of the shore district of New Jersey. His wife and two grown up daughters survive him.

New York State Medical Association.—The eighth special meeting of the Fifth District Branch of this Association was held in the city of Kingston, N. Y., July 22d. Papers were read by Dr. Thomas H. Manley, on "Pathological Changes from Traumatisms of Spine," and on "Acute Suppurative Pleurisy," by Dr. J. D. Sullivan; also the recital of a "Strange Case," by Dr. J. G. Porteus. Upon the adjournment of the meeting the members took an excursion to the Hotel Kaaterskill, Catskill Mountains, and were the guests of Mr. Harding, the proprietor. There was a large attendance of members and a profitable meeting.

Lister as the Genius of Surgery.—The new Policlinic in Rome will have its two façades adorned with bass-reliefs in illustration of the modern genius of medicine: John Baptist Morgagni, representing pathological research, and Sir Joseph Lister surgical treatment. Designs for the bass-reliefs in question have been sent in by twenty-one competing sculptors, and are this week on view in the Scuola Vittorino da Feltre, in the Via della Polveriara. The number of designs is thirty-six, several artists having submitted more than one to the "Comitato Aggiudicatrice." The committee, which is composed of an equal representation of fine art and medicine, under the presidency of Dr. Guido Baccelli, has no easy task before it, as the competitors include the acknowledged masters of sculpture in Italy.—*The Lancet.*

Society Reports.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-sixth Annual Meeting, held at Hotel Kaaterskill, Catskill Mountains, N. Y., July 16 and 17, 1890.

THE Society was called to order by the president, DR. HASKET DERBY, of Boston.

Brain Tumor with Interesting Eye Symptoms.—The first paper was that of DR. W. F. NORRIS, of Philadelphia, reporting two cases of "Brain Tumor with Interesting Eye Symptoms."

CASE I.—Mrs. X——, aged thirty-two, a strong and vigorous woman, was seen in June, 1889. During last few months there had been failing eyesight, no double vision, movements of lid and ocular muscles good. Right pupil responded promptly to light. The left was slower in its response and was larger than the right. The ophthalmoscope showed a low grade of hypermetropia and hypermetropia astigmatism. Disks normal. The field of vision in left eye was defective in upper outer quadrant. In the right eye the defect was in the upper and inner quadrant, but not so marked.

April 4th.—Had a slight convulsion. She began to have pain referred to the right side of the head and eye.

May 6th.—Right optic disk beginning to be hazy and slightly prominent. Left disk also swollen. Both pupils sluggish. Twitching of muscles of shoulder. Increased headache, nausea without vomiting. Diplopia was first noted May 18th. She was seen by Drs. William Osler and S. Weir Mitchell in consultation and diagnosis of a tumor of the base, probably near the optic thalamus, was made.

June 3d.—There was a convulsion followed by nystagmus. Death occurred July 5th. The diagnosis was confirmed by the autopsy, microscopical examination showed the characteristic appearance of glioma.

CASE II.— Mrs. Y——, seen in January, 1889. She had lost the sight of one eye and was rapidly losing that of the other. A year previously she was seized with deafness in the right ear. Six months later she had an attack of severe pain in the right trigeminus. Later there was double vision and gradual failure of sight. The right eye was slightly prominent, the pupil semi-dilated and irresponsive to light. There was paralysis of the external rectus muscle. There was in the right eye a dense grayish haze of the retina, most marked about the nerve. The disk was slightly in advance of the retinal level. In the left eye vision was diminished and there was a semi-transparent haze in front of the disk. There was loss of smell on the right side of the nose, and the skin and mucous membrane on this side were less sensitive than on the other. There was absolute deafness on the right side. Six days after this observation vision in the left eye was entirely lost. The patient then returned to her home. There was increased suffering from headache and intense neuralgia in the superior and inferior dental nerves, especially on the right side. A few days before death the right eye became so prominent that the lids could not close over it. June 10th, the patient became comatose and died.

The autopsy showed a large, firm tumor occupying the sella turcica, extending on each side along the wings of the sphenoid, especially on the right side, and also toward the base of the skull. The growth was a carcinoma, and involved the second, third, fourth, fifth, sixth, seventh, and eighth nerves on the right side, and the second and third on the left side.

Intracranial Neoplasm.—DR. CHARLES A. OLIVER, of Philadelphia, gave the history of a case of "Intracranial Neoplasm with Localizing Eye Symptoms, Position of Tumor Verified at Autopsy." The patient, a male adult, presented general symptoms of right hemiplegia and right hemianæsthesia. When first seen by the writer there was right lateral homonymous hemianopsia, the left field of vision being the smaller, with well-marked Wernicke hemiopic pupillary reaction sign. In the remaining field there were floating scotomata for green, more pronounced on the left side, with slight subnormal color perception, also more marked in the left field. In the right fundus there was a broad, superficial blotch like hemorrhage, extending over the lower outer quadrant of the disk, with enlargement and tortuosity of both the retinal veins and the arteries of the same side.

This grouping of symptoms led to a diagnosis of a gross intracranial lesion near or in the left optic thalamus. Autopsy, four weeks later, showed a glio sarcoma involving the external portion of the left optic thalamus as well as the corpus striatum almost as far as its anterior third. The left optic tract as far forward as the optic chiasm was markedly flattened and pressed upon.

Transient Amblyopia with Bitemporal Hemianopsia in a Case of Malarial Cachexia, read by DR. G. C. HARLAN, of Philadelphia. A sailor, aged twenty-two, was admitted to the hospital September 2, 1889, with severe chills and fever. During the following month he exhibited varied nervous symptoms, headache, mania, hallucinations, etc. Quinine was given without any effect, with the exception of preventing a recurrence of the chills.

November 14th.—There was diminution of sight, and the patient could see only in front. Vision existed only in the nasal fields.

November 18th.—Patient was entirely blind. The next day there was some return of vision. Microscopic examination of the urine showed pigmented corpuscles in great number. Quinine, twenty-four grains daily, caused rapid improvement. Vision rapidly returned and on the 24th was normal. By the 30th the pigmented corpuscles had disappeared. There was no return of the symptoms.

The Extraction of Dislocated Lenses from the Eye, whether Transparent or Cataractous, a paper by DR. C. S. BULL, of New York. The author maintained that in the majority of cases it was possible to extract a lens dislocated into the vitreous by external manipulation without the introduction of any instrument into the eye. The manipulation may be described as follows: The lids are held open by a wire speculum, and the section made upward with a narrow knife. The speculum is then removed and the upper lid lifted away from the ball with a wire elevator. Pressure is then made against the lower part of the eyeball, the pressure being made directly backward. The lens will be seen to rise and appear at the pupil. Sometimes it comes through the pupil, but occasionally the use of a blunt hook or wire spoon becomes necessary. If continued pressure fail to push the lens through the pupil or occasions prolapse of the vitreous, some other method must be substituted. For a number of years he had not found it necessary to introduce a spoon into the vitreous chamber to remove a dislocated lens floating in the vitreous.

Simple Operation for Cataract.—Dr. Bull also presented some further considerations on the "Simple Operation for the Extraction of Cataract." The paper was based upon some one hundred and sixty cases of cataract extraction without iridectomy. The method of operation and the complications liable to arise were discussed in detail. The advantages claimed were: 1, If successful without complication, the natural appearance of the eye is preserved; 2, the acuteness of vision is greater than with the older operation; 3, eccentric vision is decidedly better; 4, small particles of the capsule are less likely to be incarcerated in the wound; 5, it is a shorter operation in point of time; 6, as there is no iridectomy, there is little or no hemorrhage.

The disadvantages are that the technique is more difficult than that of the old operation, the corneal section must be larger; the section must be performed rapidly, and there is danger of the iris falling upon the knife; the cleansing of the pupillary space and posterior chamber is more difficult; posterior synechia, and incarceration and

prolapse of iris is more common. The operation is not applicable to all cases.

Double Zonular Cataract.—Dr. Hasket Derby, of Boston, reported eight cases of double zonular cataract among ten members of the same family.

Removal of a Large Exostosis of the Orbit with Preservation of the Eye, a paper by Dr. T. R. Pooley, of New York. The patient was an Irish girl, aged twenty-three, who came under observation August 21, 1888. Two years before, she had noticed protrusion of the right eyeball. At the upper inner angle of the orbit a hard tumor could be felt. A diagnosis of orbital exostosis was made and confirmed by exploratory incision. The patient then disappeared until February 6, 1890, when she returned with pronounced optic neuritis. V. = $\frac{20}{30}$. Next day there was great pain in and about the orbit with rise of temperature and mild delirium. Exophthalmos was increased and immediate operation urged. The tumor was then removed by the use of the chisel, the mallet not being required. The bony growth measured 39 × 28 × 30 millimetres and weighed 26 grammes. The patient was discharged at the end of three weeks and vision gradually increased to $\frac{20}{30}$, and all evidence of neuritis disappeared.

Operation for Ectropion of the Lower Lid by the Sliding Flap Method was the title of another paper by Dr. Pooley. The object of the communication was to show the adaptability of this operation for the relief of cicatricial contraction. The patient was a woman suffering with ectropion resulting from cicatricial contraction following the removal of epithelioma of the lower lid. The conjunctiva to the cul-de-sac was exposed. A flap was slid from the temporal region to fill the gap in the lower lid. The patient was discharged two weeks later with a perfect result.

Case of a Foreign Body Remaining in the Eye about Twenty Years, followed by Abscess in the Scleral Wall; Opened and Recovery, a paper by Dr. B. L. Millikin, of Cleveland, O. On March 18, 1871, E. M. O——, aged ten, was struck in the right eye with a bit of musket cap, which he supposed at the time did not enter the eye. Following the injury the eye was greatly inflamed, confining him to his room for nearly three months. The eye gave no further trouble, and vision was fair until 1883, when he had an attack of severe inflammation in it. The eye again improved, with fair vision, and remained well until 1887, when it again became red and painful, with failure of sight.

The patient was seen for the first time February 28, 1888. Three or four days before, another attack of inflammation had occurred. The cornea showed a linear opacity. Behind this was a slit in the iris. The ophthalmoscope showed an oblique track directly through the body of the lens. In the anterior portion of the vitreous was plainly seen a grayish-white body projecting into the vitreous. This had the appearance of an encysted body. Vision in right eye = $\frac{6}{36}$, in left eye $\frac{6}{6}$. There was tenderness on pressure over the position of the body.

September, 1889, he had another severe inflammatory attack, but was not seen until November 27th. Under active treatment the inflammation subsided.

In December an enlargement appeared over the position of the foreign body and rapidly increased in size.

January 14th.—The eyeball was free from any general inflammation, but the projection over the foreign body had increased in size. Under cocaine a needle was passed through the swelling and came in contact with a hard body. A triangular portion of the conjunctiva was then dissected off and an incision made into the swelling. Three or four drops of pus escaped. With a spoon a number of hard black particles were scraped out. As much as possible of the interior of the sac was removed with the spoon, forceps, and scissors. The sclera was at least a centimetre thick at this point. The eye recovered without a bad symptom, the body previously seen in the vitreous chamber had disappeared. By January 22d V. = $\frac{6}{6}$. Since the operation there has been no return of the inflammatory attack.

Foreign Body in the Orbit was the title of a paper by Dr. W. F. Norris, of Philadelphia, Pa.

Case I.—T. R——, came under observation on account of pain in the left forehead and orbit. The eyeball of that side was wanting. The orbit was filled with a mass sensitive to the touch and at the bottom of the cavity was an opening discharging pus. The probe detected a hard body. Patient had been struck eighteen months before by an exploding railroad torpedo, shattering the left eye, which was enucleated by a surgeon, but the orbit had never healed. The patient was etherized and a large piece of metal which had formed the shell of the torpedo was removed by forceps.

Case II.—P. B——, aged forty-seven, was struck in the eye by a piece of nail which flew from a piece of wood he was sawing with a circular saw. Some days after the accident he came to the hospital. There was an opening through the lower lid and the sclerotic conjunctiva. A minute black point was seen projecting from the eye, which was found to be metallic, and on removal it proved to be a piece of nail three fourths of an inch in length.

Complete Paralysis of the Lateral Movements of Both Eyes, Ability to Converge Remaining Intact, by Dr. B. L. Millikin, of Cleveland, O.

M. McL——, aged thirty-three, Irish laborer, presented himself March 21, 1890. Twelve years ago first noticed that he saw things double, but this passed off in a short time. This occurred occasionally since then. For the past few weeks had been much annoyed by the double images. The patient has been addicted to the excessive use of alcohol, but denies syphilis. In each eye V. = $\frac{6}{6}$. When winking, the left eye does not close as rapidly as the right. The eyes follow an object carried up and down in front of them, but in no position of the field can the eyes be seen to move laterally. When the eyes fix an object and this is carried toward the eyes, they are seen to converge so that the object may be carried to within seven or eight inches of the eyes, pupillary reaction is normal. Each optic disk was small, round, with a narrow choroidal ring, slightly deepened pearly color, and slight degree of H. There were no nervous symptoms and no history of previous illness. Ten grains of iodide of potassium three times daily was ordered, but only a few doses taken. By April 4th the lateral movement of the right eye seemed normal and that of the left eye was improving. The patient then passed from observation.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-third Annual Meeting, held at the Hotel Kaaterskill, Catskill Mountains, N. Y., July 15, 1890.

Oren D. Pomeroy, M.D., President, in the Chair.

Mastoid Sclerosis.—The first paper read was entitled "Mastoid Sclerosis, as Illustrated by a Typical and Fatal Case," by Dr. Huntington Richards, of New York.

The patient, a man, aged twenty-six, came under observation March 8, 1890. Eleven months before a large polypus had been removed from the left auditory canal. The symptoms noted March 8th were earache and headache, with some mastoid tenderness. There was apparently a cicatricial drum-membrane, greatly depressed. There was an opening in it about three millimetres in diameter. A small polypus projected through the opening. A dose of calomel was ordered and Bacon's artificial leech, followed by frequent douching, was advised. It was at this time deemed probable that an operation on the mastoid would be required. Four days later the drum-membrane had become prominent. A Politzer inflation greatly increased the prominence. There was no redness or stenosis of the wall of the auditory canal. The

drum-membrane was adherent to structures posterior by a line along its middle, dividing the prominence into two portions. Three days later a portion of one of these prominences was removed by the snare. Three days later still (18th), the auditory canal was much stenosed. There was swelling and tenderness in front of the ear, and some tenderness over the mastoid tip. The artificial leech was again applied with benefit.

May 1st.—A polypus that had formed was removed.

May 3d.—There was again mastoid tenderness. Discharge became profuse.

May 5th.—The mastoid was operated on, but no trace of pus or of any true antrum was found.

May 10th.—The temperature rose to 104.2° F. and the patient complained of violent headache.

May 12th.—The attempt was made to extend the opening forward toward the tympanum by the use of Volkmann's spoon, without result. The opening was then enlarged by chisel and rongeur forceps, until it became funnel-shaped, measuring 27 mm. in depth and 27 × 20 mm. in width. No antrum was discovered and no recognizable drum cavity was opened, and no accumulation of pus tapped. The day following the operation muttering delirium set in, with diplopia, and some slight convulsive movements of the orbital and facial muscles. Complete ptosis of the left eyelid and persistent tonic contraction of the muscles of the right side of the neck. The patient continued to fail, and died at 4.30 P.M., unquestionably of diffuse meningitis, and, not improbably, there was an intra-cranial abscess. No post-mortem could be obtained. It is possible, though far from certain, that an early and thorough operation for removal of the ossicles and pus-confining membrane would have accomplished what the two mastoid operations failed to do, viz., adequate outlet for pus, etc., and consequent saving of life.

In his paper the author urged the adoption of the expression "vault of the tympanum," or "fornix tympani," to designate that portion of the drum cavity above the upper border of the tympanic ring. This term is quite as appropriate as is the half-facetious, though conveniently brief "attic" of several recent writers. As to a supposed, and most erroneously supposed, Latin equivalent of the latter, viz., "atticus," it is hardly necessary to say that it is wholly inadmissible on linguistic grounds, there being no noun "atticus" in the Latin language, save the adjectival substantive used to designate an Athenian citizen. "Atticus" is not, never was, and cannot now be made the Latin term for a garret, attic, or upper story of a house.

Septum Resembling Tympanal Membrane.—DR. S. THEOBALD, of Baltimore, reported a case in which a septum, closely resembling the tympanal membrane, formed in the middle third of the external auditory canal and was removed with improvement to hearing. The septum, which was present only in the right ear, was about six millimetres nearer the outer extremity of the auditory canal than was the tympanal membrane of the opposite ear. It evidently had no connection with the ossicles, but moved out when the middle ear was inflated by the Valsalva method, and moved in again during the act of swallowing. There was a history of double otorrhœa in childhood. After excision of the septum it was found that the tympanal membrane proper was entirely destroyed, but the stapes and malleus were recognized *in situ*. The mucous membrane of the tympanal cavity was sclerosed and atrophied. A marked improvement of hearing followed immediately upon the removal of the septum. Further improvement was subsequently gained by inserting an artificial (cotton) drum-head. The hearing, which before the operation was equal to distinguishing words in a loud voice at twenty feet, was improved to words in a low voice and whisper at twenty feet. The septum showed a decided tendency to re-formation which had to be controlled by the application of chromic acid and a second resort to the knife.

Discussion.—THE PRESIDENT: These membranes forming in the external canal have for their end a reparative action. I saw such a membrane form in a case of my own where there had been otorrhœa with loss of most of the drum-membrane for fifteen years. The discharge ceased under treatment, and there was the formation of a new membrane similar to that described by Dr. Theobald, only in my case it was much thicker. I consider that in most cases the formation of this membrane is a most satisfactory reparative result. I should be glad to see Dr. Theobald's case followed for some time to see whether or not there was any return of disagreeable otorrhœa.

DR. J. A. ANDREWS, of New York: A few years ago I reported to the Society a case similar to that of Dr. Theobald. The membrane closed about three-fourths of the canal. It was removed and there was no return of the discharge.

DR. HUNTINGTON RICHARDS, of New York: I recently saw a case in which there were two closures. One at nearly the normal distance of the tympanic membrane and the other close to the meatus. I removed the outside membrane, but hesitated to cut through the other, as in one or two cases where I have done so, the evidences of improvement have not been great. I am now treating a similar case where the stenosis is close to the position of the normal tympanic ring. I have cut away the lower portion of the ring with acetic acid to permit free exit of discharge.

DR. THEOBALD, of Baltimore: There was no return of the discharge in the few weeks that the patient remained under observation. The patient would undoubtedly have been willing to be more or less troubled with otorrhœa to gain the marked improvement in hearing.

On the Renewed Employment of the Nasal Douche and Kindred Procedures, by DR. A. H. BUCK, of New York. Several years ago attention was called to the danger of exciting ear trouble by the use of the nasal douche and similar procedures. For some time it seemed that this warning had been heeded. During the past winter and spring the author had seen a large number of these cases and thought it advisable to again call attention to the dangers that may follow the use of the nasal douche. In a few instances the results of the inflammation have been severe, but in the majority they have been simply an increase of the subacute nasal and aural catarrh.

As a safer and equally efficient method of treatment the use of a spray was suggested. The following preparations were mentioned:

℞. Eucalyptol,
Ol. gaultheria ..... āā gr. j.
Menthol ..... gr. ij.
Benzoinol ..... ʒ ij.
M.

If the patient objects to this, it may be substituted by

℞. Listerine ..... 1 part.
Water ..... 3 parts.

In the presence of an accumulation of viscid mucus or of crusts, a stream of flowing water will doubtless prove more effective than a stimulating spray. If the latter is used freely, and each time during the inhalation of a deep breath, crusts and mucus will speedily cease to play a part in the therapeutic problem. In no instance had he known the use of the mixtures mentioned to cause any unpleasant aural symptoms, the use of sprays must, however, be looked upon only as a valuable method of supplementary treatment, and not as a therapeutic procedure of the first order.

The Removal of a Bullet from the Ear with the Assistance of the Galvano-cautery, by DR. LUCIEN HOWE, of Buffalo, N. Y.: The difficulty occasionally met with in removing a round hard body from the auditory canal is well known. The first efforts in these cases should be made with a syringe. The writer wished in this paper to call attention to a method which may occasionally prove

useful, and which, so far as he was aware, had not been before suggested.

April 30th, a boy, aged seven, was brought to him with a small bullet lodged in the lower part of the auditory canal. An attempt to remove it by syringing was first made without avail. An attempt with forceps showed the foreign body firmly imbedded, and on account of its smooth surface, it was impossible to grasp it. It then occurred to the operator that it might be possible to melt into the lead the wire of a galvano-cautery by means of which, when cool, it could be removed, or if not, to at least roughen the surface to such an extent as to allow forceps to grasp the bullet firmly. The child was put under the influence of chloroform, and the wire was melted into the lead, and the ball was drawn to the narrow part of the canal, where it became detached, the surface of the bullet was then roughened above and below, and with toothed forceps removed.

The speaker took the opportunity offered by the report of this case to express his firm conviction that we should use every effort to discourage the practice common among physicians of attacking every such foreign substance with a pair of forceps. By our own example and discussions we should teach our brother practitioners how much simpler and safer an instrument we have in the syringe.

Anatomy of the Elephant's Ear.—Dr. A. H. Buck, of New York, made a supplementary report on the "Anatomy of the Elephant's Ear."

Excision of Malleus and Membrana Tympani.—Dr. C. H. Burnett, of Philadelphia, read a paper on "Permanently Good Results of Excision of the Malleus and Membrana Tympani in a Case of Chronic Tinnitus and Aural Vertigo; and in a Case of Chronic Suppuration of the Attic, due to Necrosis of the Head of the Malleus." In the first case all known remedies for the relief of catarrhal deafness, tinnitus aurium, and vertigo failed to give any relief. The malleus being found adherent to the promontory, this was believed to be the cause of the retraction of the chain of auditory ossicles, impaction of the stapes, pressure on the labyrinth fluid, and the noises in the head and intense aural vertigo.

The patient was therefore etherized, May 22, 1888, and the membrana tympani and the malleus excised. The relief to the tinnitus and vertigo instantaneous and complete and the cure has been a permanent one for two years, thus proving the mechanical origin of so-called Menière's disease in many instances.

In the second case a chronic purulent discharge from the attic cavity of the middle ear, due to necrosis of the head of the malleus of several years' duration, was promptly and entirely relieved by excision of the membrana tympani, and the diseased malleus. The operation was performed in July, 1889. The purulent discharge ceased at once. A new membrane formed in the course of two months and the hearing rose from nothing to twelve feet for isolated words. There has been no renewal of the discharge up to the present time, one year from the date of operation, and the general health of the patient has greatly improved.

Shrapnell Perforation.—Dr. B. Alexander Randall, of Philadelphia, contributed further notes on the Shrapnell perforation. He remarked that in citing in his paper of the previous year a series of 13 new cases among 500 patients in six months' practice and a total of 120 among 10,000 in a group of clinical workers, he had thought the frequency of the lesion sufficiently proven; yet as the point had been questioned when his paper appeared, he had been noting such cases again since January 1st. As the result, he had 23 cases to report, observed among 500 new patients of the six months, three of which occurred in patients previously seen but without recognition of such a perforation. His incomplete notes for the latter half of 1889 showed only 4 records of the lesion. But he was confident that many more had been seen and treated. Yet even accepting this record as complete, it furnished a series of 27 cases, among about 1,000; or 42 among the 1,500 patients seen during fifteen months = 2.8 per cent.

Excision of the drum membrane and malleus had been done in two of the cases before reported, without any such brilliant result as to lead him to prefer this radical measure to the intra-tympanic syringing usually employed. He expected to adhere to the latter, using as before the aural syringe and the hollow lachrymal probe as the most satisfactory apparatus, and the peroxide of hydrogen and weak solutions of the mineral acids as the fluids.

The cases were reported in detail, with drawings of many of them and the farther history of the former cases was appended.

Mastoiditis Interna following Erysipelas.—Dr. J. A. Lippincott, of Pittsburg, reported a case of "Mastoiditis Interna Purulenta following Erysipelas." The ear became involved one week after the occurrence of a severe attack of erysipelas. There was no preliminary involvement of the throat or nose. The patient recovered after opening of the mastoid and syringing.

Dr. Neil J. Hepburn, of New York, reported a case of "Fracture of the Malleus Handle from the Introduction of a Hair-pin."

Some Cases of Mastoid-cell Disease with a Fistulous Opening which Recovered Without the Use of the Drill or Chisel, by Dr. Oren D. Pomeroy, of New York. Four cases were reported in which recovery occurred by the use of Wilde's incision and careful antisepsis.

The first case was that of a woman, forty-nine years of age, who had a fistulous opening into the mastoid three-quarters of an inch deep. After waiting a reasonable time for the fistula to close from the bottom, the external wound was allowed to close. There was no untoward results.

The second case was that of a man, thirty-nine years of age, who had a fistula into the mastoid eleven-sixteenths of an inch deep, which healed before the external wound was closed.

The third case was that of a child, four months of age, who had an opening into the mastoid, extending forward and inward for one and a half inch. This had nearly closed when the external wound was allowed to close.

The fourth case was that of a man, twenty-two years of age, who had an opening into the apex of the mastoid, which closed concurrently with the Wilde's incision.

None of these cases had enough systemic disturbance to suggest that anything was going wrong.

Aneurism First Recognized in the Fundus of the Ear, Later Appearing in the Neck, a paper by Dr. Charles A. Todd, of St. Louis. May, 1880, Mr. C——, aged forty-five, came under observation, complaining of pain in the left ear and symptoms suggesting furunculus. In 1858 he had had severe otitis media in both ears for one week followed by discharge, which ceased without treatment. Some deafness has existed since. For the past seven or eight years he had noticed a pulsating sound, at first in both ears, now in the left. On examination of the left ear, there was seen a circumscribed swelling on the floor of the meatus, just in front of the membrana and entirely concealing it. It was soft and fluctuating. Filling the ear with water, a distinct intra-aural pulsation could be seen. The swelling was lanced under the supposition that it was a furuncule. There was a free gush of blood, and three ounces were lost before the flow could be stopped by tamponing. No pus whatever was seen. The tampon could not be permanently removed for several days. Compression by tampon was advised to be continued at home. August, 1880, it was learned that compression had afforded little benefit. Ligation of common carotid was suggested if symptoms were considered sufficiently severe.

March, 1883, patient was again seen. Electrolysis had been tried with asserted diminution in size. March, 1890, the aural tumor was still present, but in addition there was a large aneurismal swelling of the neck below

the ear. The patient was then referred to a general surgeon, and has not since been heard from.

Dr. Blake's Paper Disk. Case Histories. a paper by DR. ROBERT BARCLAY, of St. Louis. The object of the paper was particularly to call attention to the application of paper dressings to the membrana tympani, first suggested by Dr. Clarence J. Blake, of Boston, for the treatment of perforation of that structure. To demonstrate not only the advantages claimed for this method, but others modestly disclaimed, and its wider usefulness in other conditions than those defined for its application when originally suggested, the following cases were reported.

CASE I.—A lady, twenty-eight years of age, with right sided acute otitis media of twenty-four hours' duration. The right membrana tympani vibrans was found bulging. A deep incision afforded some relief. At the end of five days the perforation of the posterior superior quadrant of the membrana tympani. This was closed by the application of a paper disk. Seven weeks later the disk, with attached epithelial plate, was removed from the superior posterior canal wall. The perforation had healed, and hearing was normal.

CASE II.—A lady, twenty-five years of age, sought relief from tinnitus and deafness of right ear. The left ear had been condemned as irreparably disabled by former inflammation. She had had otorrhœa in childhood. Three years before, there had been a return of this trouble in the left ear. This was checked after one week's duration. This ear, however, remained deaf. With the right ear she could hear a moderate voice, with the left a loud voice at two feet. Right middle ear was the seat of chronic catarrhal inflammation. The membrana tympani of the left ear was perforated in the posterior inferior quadrant. Treatment somewhat relieved the symptoms in the right ear. Stimulating applications to the perforation induced its closure to one-sixteenth inch diameter, when a paper disk was applied. Two days afterward the disk was still in place. Hearing in left ear was $\frac{1}{4}$; while moderately loud voice could be heard at twenty-five feet distance. The disk was subsequently removed, and the perforation closed. The hearing of left ear has steadily improved.

CASE III.—A man, thirty-five years of age, was seen, with deafness, tinnitus, cough, and otorrhœa in left ear of two months' duration. Two circular perforations of the membrana tympani were found. The otorrhœa was checked and a paper disk applied to each perforation with immediate improvement of hearing for the voice. It is thought that the relief may have been permanent, as the patient did not return.

CASE IV.—A woman, thirty seven years of age, six weeks before coming under observation sustained a compound fracture of the skull, involving both sides of the base, the bony tympana, membranal tympanum, and right external auditory canal. There had been aural hemorrhage, followed by otorrhœa. There was a transverse rent of right membrane. Within thirty-five days the only open wound was a small perforation. A paper disk was applied; a little flexible collodion was painted over it. Within two weeks hearing became normal.

CASE V.—A woman, twenty-one years of age, with the left membrane almost entirely sloughed away. A paper disk was applied. Within ten days the watch could be easily heard off the left auricle. The hearing has steadily improved.

CASE VI.—A man, twenty-two years of age, had prolonged otorrhœa on right side in childhood. For past three weeks had deafness in both ears. Left ear was the seat of chronic catarrhal otitis media. Right ear shows two perforations. These closed in seven weeks. There was marked improvement of the hearing.

CASE VII.—A male, nineteen years of age, had been subject to bilateral otorrhœa since the age of six months. Perforation of right membrana tympani was found. After cessation of otorrhœa paper disks were applied. The perforation promptly closed with improvement of hearing.

CASE VIII.—A male, nineteen years of age, had otorrhœa in childhood. During past eight years has had recurring attacks of otorrhœa on left side. The left membrana tympani was greatly thickened and perforated. The discharge ceased in nine days and under stimulating treatment the size of the opening diminished. In the fourth week the first paper disk was applied. Four days later the hearing for the watch was $\frac{3}{4}$. The perforation subsequently closed.

CASE IX.—A physician, forty-eight years of age, had sustained a rupture of both tympanic membranes in diving thirty four years before, and for over thirty years had intermittent otorrhœa. A perforation in the right membrana tympani was found. This promptly healed under the application of a paper disk. The hearing greatly improved.

Conclusions.—From the case histories given may it not be considered demonstrated that Dr. Blake's paper-dressings have these therapeutic advantages already claimed: Applied to a perforation of the membrana tympani it performs in a great measure the functions of the lost membrane—1, improving the hearing from the time of application; 2, maintaining a normal degree of moisture and temperature in the air of the tympanic cavity; 3, protecting the inclosed tissues from direct influences of atmospheric changes; 4, excluding organic and inorganic foreign bodies approaching from the external auditory canal; 5, it acts as a local irritant to the edge of the perforation only, thereby inducing reproduction of the lost membrane; 6, as a splint, protecting it when forming and preventing its displacement in either direction.

May we not accredit this method with these additional advantages, hitherto unclaimed: 1, Improvement in hearing may subsequently result from cicatricial closure of the perforation, not at once appreciable on application of the paper disk; 2, the paper dressing may prove serviceable even where the perforation is quite large; 3, it may be used to advantage where indeed the outer surface of the membrana tympani has not returned to its normal condition; 4, it may prove a serviceable artificial membrana tympani where that structure is almost entirely lost; 5, at the same time may stimulate reproduction thereof; 6, it may serve as a splint when applied to manometric tissue; 7, it may induce conservative structural modification thereof; and, 8, may by acting here as an artificial membrana tympani at the same time improve the hearing.

A failure to secure satisfactory results is not to be attributed to the method, experience proving that discriminating judgment and skill in its application are largely essential to its usefulness.

Election of Officers.—The following officers were elected: *President*—Dr. Gorham Bacon, of New York; *Vice-President* — Dr. Huntington Richards, of New York; *Secretary-Treasurer*—Dr. J. J. B. Vermyne, of New Bedford, Mass.; *Committee on Membership*—Drs. Arthur Matthewson, of Brooklyn; Samuel Theobald, of Baltimore; and S. D. Risley, of Philadelphia; *Committee on Publication*—Drs. J. J. B. Vermyne, of New Bedford; Dr. C. J. Blake, of Boston, and Dr. J. Orne Green, of Boston.

The following were elected to membership: Dr. Frederick L. Jack, of Boston; Dr. J. B. Shapleigh, of St. Louis; Dr. Benjamin J. Baldwin, of Montgomery, Ala.; Dr. J. M. Ray, of Louisville, Ky., and Dr. F. W. Ring, of New York.

The Society then adjourned.

An Injection for Fistulæ.—The following is recommended as of much service in promoting a cure of fistulous tracts:

℞. Camphor ..... ʒ j.
Salol ..... ʒ ss.
Ether ..... ʒ j.

Correspondence.

THE BINDER.

To the Editor of the Medical Record.

Sir: In the editorial columns of the Medical Record of May 31st, the binder is given a "header" of no uncertain character. Notwithstanding the unseating of the practice so long continued in so cyclonic a manner, there will still remain some who believe the binder both scientific and physiological, and in a large number of cases productive of comfort. It is not applicable to all cases equally. Women with thin abdominal walls do not derive the good that comes to those with full habit. No one will claim the binder exercises other than a general effect upon the uterine circulation. It should never be connected with the napkin, as the upward tendency will tighten the napkin so as to seal the vagina and prevent the free lochial discharge.

First, as to its scientific character, effect upon involution, etc. There exists, in a greater or less degree, the same indications for supporting the abdomen and its viscera after confinement as in the tapping the abdomen when distended with fluid. The rapid removal of so great pressure and distention is followed by an influx of blood and passive congestion of the whole abdominal and pelvic viscera, at times producing flatulence and lack of ease. The binder by its support relieves this disposition, and thus favors better functional activity of all these organs.

There is no question in my mind touching its favorable influence upon involution of the uterus and abdominal walls, especially the latter. Its effect upon the uterus is limited to its effect in modifying the pelvic and abdominal circulation. In all instances when the patient is possessed of any degree of embonpoint, pregnancy creates a great redundancy of tissue in the abdomen, and if the pregnancies are near together the excess multiplies with each. The result is that the walls grow pendulous. This condition creates a function in these walls—to wit, their own support, and thus tends to bar absorption and the return in *statu quo*. The binder removes the pendulous character, placing the whole at rest, and thus deprived of function it straightway begins involution. I have a patient whose abdominal wall from some cause unknown to me slid down like an apron over the pubis upon the thighs, causing vomiting and distress in the stomach. Proper support has entirely restored the normal condition.

If the corset can work so great changes in the form, why not the binder influence favorably. The fact is, it does, and the majority of women express themselves as more comfortable after its application, and for the reason heretofore specified, and not imagination. If the practice is scientific, it is physiological. R. W. Erwin, M.D.

Bay City, Mich.

An Original Emergency Obstetric Forceps.—At the recent Nashville Convention many stories were told by those in attendance, while comparing notes concerning professional experiences. One practitioner, Dr. W. C. Blackman, of Davidson County, Tenn., related his experiences in two obstetric cases. In both instances he decided that immediate delivery was necessary. The natural forces had given out. He had no forceps with him; no neighbors to call on for assistance, and he was miles from home. Fortunately in both houses there happened to be pairs of shoemaker's pincers with stout curved handles. The latter were slipped over the heads of the children, and by pulling against the pivoted lock successful extraction was made. Both mothers and both children made perfect recoveries. One of the latter had a scar just at the edge of the hair, but the growth of the latter (the child being a girl) soon covered it up. This girl grew up into blooming womanhood and was married the week before the convention met.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 14 to July 19, 1890.

Phillips, John L., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for two months. Par. 4, S. O. 164, Headquarters of the Army, A. G. O., Washington, D. C., July 16, 1890.

Corbusier, William H., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for four months on surgeon's certificate of disability, with permission to leave the Division of the Missouri. Par. 4, S. O. 162, A. G. O., Washington, D. C., July 14, 1890.

Page, Charles, Colonel and Assistant Surgeon-General, Medical Director of the Department. Granted leave of absence for one month, to take effect the 30th instant. Par. 3, S. O. 91, Department of the Missouri, St. Louis, Mo., July 14, 1890.

Arthur, William H., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for three months, to take effect September 15, 1890, or as soon thereafter as his services can be spared. Par. 1, S. O. 160, A. G. O., Washington, D. C., July 11, 1890.

Means, Louis M., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted on surgeon's certificate of disability, in S. O. 4, January 6, 1890, from this office, is extended six months, on account of sickness. Par. 16, S. O. 160, A. G. O., Washington, D. C., July 11, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 19, 1890.

Auzall, E. W., Assistant Surgeon. Detached from the Galena and to wait orders.

Eckstein, A. C., Surgeon. Granted leave of absence for month of August.

Penrose, T. N., Medical Inspector. Granted leave of absence for two weeks.

Cabell, A. G., Passed Assistant Surgeon. Granted leave of absence for month of August.

Ashbridge, Richard, Passed Assistant Surgeon. Granted one month sick leave.

Heyl, T. C., Surgeon. Granted leave of absence for month of August.

Cooke, George H., Medical Inspector. Detached from the Navy Yard, League Island, and ordered to the Pensacola.

White, C. H., Medical Inspector. Detached from the Pensacola, to proceed home, and await orders.

Hochling, A. A., Medical Inspector. Detached from the Naval Hospital, Washington, and ordered to the League Island Navy Yard.

Wells, H. M., Medical Inspector. Detached from the Museum of Hygiene, and ordered to the Naval Hospital, Washington, D. C.

Whitfield, James M., Assistant Surgeon. Ordered to the Ajax and other monitors.

Woolverton, Theron, Medical Inspector. Ordered to the Philadelphia.

Lovering, P. A., Passed Assistant Surgeon. Detached from the Wabash and ordered to the Philadelphia.

BAILEY, T. B., Assistant Surgeon. Detached from the St. Louis and ordered to the Philadelphia.

WHITE, S. S., Passed Assistant Surgeon. Ordered to the Marine Rendezvous, San Francisco, Cal.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 19, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	28	5
Scarlet fever	43	7
Cerebro-spinal meningitis	2	1
Measles	212	11
Diphtheria	42	13
Small-pox	0	0
Varicella	7	0
Pertussis	0	0

Unna on the Treatment of Leprosy.—Unna, at Wiesbaden, in April, 1885, drew attention to the treatment of leprosy by ichthyol internally, and the application externally of an ointment of resorcin, twenty per cent., or rather of resorcin muslin. Milton has recently, in a pamphlet, drawn attention to the cure of a case of his by the same treatment, and advises that it should be extensively used, as it is efficacious, economical, and safe. Brooke, in an account of a recent visit to Unna's clinic, states that chaulmoogra oil is useless except in large doses, which the stomach will not tolerate, the treatment employed in two cases at present under Dr. Unna's care being, chrysarobin internally, with pyrogallol externally. The chrysarobin is given in a keratin-coated pill, which would not dissolve till it reached the alkaline media of the upper gut, and thus the premature oxidation, as well as the undesirable local action of the chrysarobin on the stomach would be avoided; and, in order to prevent its conversion there into chrysophanic acid, it is mixed with calcium sulphide in the pill, and followed down by free doses of hydrochloric acid.

The Art of Medicine *vs.* the Science.—What Emerson said of the poet is applicable in its degree to the true physician: "As the eyes of Lynceus were said to see through the earth, so the poet turns the world to glass, and shows us all things in their right series and procession. For through that better perception, he stands one step nearer to things, and sees the flowing or metamorphosis. . . . . The poet alone knows astronomy, chemistry, vegetation, and animation, for he does not stop at these facts, but employs them as signs." It is not enough for the physician to know anatomy, physiology, chemistry, and pharmacology; he must not stop at knowing these, but must put them into the alembic of his brain, and transmute them into medical science. Professor Huxley said the other day that it would be simply manslaughter for a doctor to treat his patients on the raw and undigested principles of physiology. Medicine must, therefore, never be looked upon as a mere science, because it is much more than that; it is wisdom sublimated from many sciences; and this is why the Gulls, the Jenners, and the Clarks can never be as common as the mere scientists who work by rule and scale. When Coleridge was accused of plagiarizing in his "Hymn to Chamouni," from the poem of Frederica Brun on the same subject, it was easily explained that though he had taken her framework and used certain of her ideas, he had done so simply to glorify and endow them with life. With her they were dead phrases; Coleridge created the "Hymn to Chamouni" out of them. Just in proportion as the physician can create diagnosis and treatment for the cases which come before him as living and as various as the patients which are the subjects of the different diseases, just by so much is he a true physician. The inferior mind may see the same things as the superior, but the latter alone "sees their flowing and metamorphosis." This is why patients would go and talk to Sir William Gull and derive benefit from the conversation, though they came away with no prescription, and took no drugs from his hands. The vulgar mind cannot understand the reason of this, and the hard scientist smiles a little superiorly at the idea.—*British Medical Journal.*

The Lunier Prize.—The French Temperance Society has received a gift of $200 from Madame Lunier, to be offered as "The Lunier Prize" for the best essay on the following questions: "What are the consequences of hereditary alcoholism, and what are the best means of prevention, or means to limit or lessen its effects?" Authors are expected to follow out the lines of inquiry suggested in Lunier's work on alcoholism. All manuscripts should be received before December 31, 1890, and should be addressed, Dr. Motet, Secretary-General of the French Temperance Society, 161 rue de Charonne, Paris, France.

A Ptomaïne of Mumps.—Dr. A. B. Griffiths has succeeded in isolating a ptomaïne from the urine of a patient suffering from mumps. The disease in this instance had attacked the parotid and submaxillary glands. The ptomaïne was obtained in white prismatic crystals, forming a crystalline hydrochloride. It was found to be soluble in water, ether, and chloroform. It gave precipitates with the common alkaloidal reagents, none being particularly characteristic. That with potassio mercuric iodide was of a slight yellow color, and the phospho-molybdate one of golden yellow. An analysis indicated that the formula of the principle is $C_5H_{13}N_3O_2$, and further examination pointed to the probability of its being propylglycocyamin.

$$HN{=}C{<}\begin{matrix}NH_2\\N(C_3H_7).CH_2CO_2H.\end{matrix}$$

It is therefore closely related to creatin (methylglycocyamin). The principle was found to be poisonous, causing in a cat nervous excitement, cessation of the salivary flow, convulsions, and death.—*The Medical Age.*

The Influence of Russian Baths on the Assimilation and Metabolism of Calcium, Magnesium, Potassium, Sodium, and Iron in Healthy Subjects.—Dr. Grüzdeff, of St. Petersburg, describes a series of investigations which he has carried out in Professor Manassein's clinic, in order to throw some light on the still obscure systemic functions in question. The experiments were conducted on eight healthy men (including the author himself), aged from twenty-one to forty-four. Each observation lasted ten days, during five of which a Russian bath of one hour's duration was taken once daily. The diet consisted of bread, meat, milk, and tea with sugar. The following are the main conclusions: 1. Russian baths increase the assimilation of calcium, magnesium, sodium, and iron, but depress that of potassium. 2. They manifest a diametrically opposite influence on the metabolism of the metals; that is, they decrease the metamorphosis of calcium, magnesium, sodium, and iron, but markedly augment that of potassium. 3. In other words, the bath promotes the retention of calcium, magnesium, sodium, and iron within the system, while it—*sit venia verbo*—expels potassium from the organism. 4. In view of these facts, Russian baths may find a useful application in the treatment of the so-called "mineral starvation."

An Unprofitable Field for the Patent Medicine Manufacturer.—There is a law in Bulgaria to the effect that if a patent medicine, which is advertised to cure a certain malady, fails to do so, the vendor of the remedy is liable for damages, and may also be sent to prison for a limited period of time as a punishment for publishing an untruth to the injury of the public.

Supernumerary Mammæ.—Dr. J. Herbert Darey, of Granger, Minn., reports an instance of this condition. In addition to the two normal breasts there was in each axilla a mamma as large as a lemon, having a distinct areola but no nipple. The ducts opened in the areola. The glands had the ordinary consistence of the normal breast, and were freely movable under the skin.—*Montreal Medical Journal.*

French Population Statistics.—The last French census showed that the population of France consisted of 37,930,759 souls. A contemporary has analyzed the figures supplied by the census returns as to occupations, and from its report it is found that the number of persons depending upon agriculture was 17,698,402; upon industrial pursuits, 9,289,206; trade, 4,247,764; liberal professions, 1,094,233; transport service, 1,020,721; public administration, 711,027; public forces, 613,362; independent persons, 2,295,966; giving a total for the classified population of 36,970,681. The difference is made up by 490,374 persons not classed, 237,899 persons without professions, and 231,805 persons with unknown professions. The mean proportion of the agricultural classes to the total population is forty-eight per cent. for the whole of France, but it varies from 83.6 per cent. in the Department of the Lozère to 2.3 per cent. in that of the Seine. The proportion of the agricultural population is much larger in the centre and west of France than in the north and east. The agricultural and industrial classes in France absorb together three-fourths of her total population, and they are distributed in inverse ratio to each other. The mean proportion of the industrial population of France is twenty-five per cent., but it is not found in any department, the nearest proportions being twelve and twenty-six per cent. The average extent of the French trading classes is eleven and a half per cent. of the total population. The following departments are essentially commercial: Seine, 27.5 per cent.; Bouches-du-Rhône, twenty-five per cent.; Rhône, twenty-two per cent.; Alpes-Maritimes and Isere, nineteen per cent.; Gard and Seine-Intérieure, seventeen per cent.; Hérault, Nord, and Seine-et-Oise, sixteen per cent. The proportion of the liberal professions to the total population of France varies but little in the several departments. Its mean is about five per cent. of the population. Finally, as to the class of the population described as independent, its mean proportion over the whole of France is eleven and a half per cent. We find the highest percentages in the following departments: Seine-et-Oise, 22.3 per cent.; Haute-Garonne, fifteen per cent.; Seine, twelve per cent.; Seine-et-Marne, eleven per cent. The lowest mean (from one to three per cent.) of persons living on their property is found in the Auvergne, Alps, Savoy, and Brittany.

Puerperal Mastitis.—Dr. M. Deis has collected a long series of cases of puerperal inflammation of the mammary glandular tissue, and embodied his researches in a thesis published last year at Heidelberg. About 3.6 per cent. of lying-in women were attacked, the majority being primiparæ. In half the cases the inflammation subsides without suppuration. Mastitis begins, as a rule, between the eighth and tenth day, and lasts from three to five days. The outer and externo-inferior lobes of the gland are the most frequently attacked. The temperature ranges from 100° to 104°, the maximum being usually attained on the first day of illness.

Music and Meat.—It is said that Adelina Patti habitually uses large quantities of a preparation of beef, believing that it tends to preserve her voice and quiet her nerves when overstrung.

Hearing Restored in a Deaf-mute.—Dr. W. H. Bates reports, in the New York *Medical Journal*, the case of a deaf-mute, nineteen years of age, whose hearing had been lost after an attack of cerebro-spinal meningitis, at the age of three years. The patient could not hear the ticking of the watch, loud conversation, or the sound of her own voice. The Eustachian tubes were not easily opened by Politzeration. Drum-membranes transparent, slightly sunken. Tinnitus was present. The history of the patient, deafness following cerebro-spinal meningitis, would have indicated incurable internal ear deafness, and the negative appearance of the drum-membranes would have supported this supposition. The tuning-fork, however, gave the well-known formula obtained in many uncomplicated cases of catarrhal inflammation of the middle ear, a condition that can often be benefited by treatment. Treatment was pursued daily for a month by inflation and the application of nitrate of silver to the vault of the pharynx. Her family physician was giving her constitutional treatment. At the end of three months the watch could be heard at a distance of five feet, and conversation at twenty feet, the patient was learning to talk, her speech resembling that of a young child.

Cooking Eggs.—How many women know how to prepare a perfectly fresh egg so that an afflicted stomach can eat it? Pour boiling water over the egg (in its shell), let it stand on the tank in the water for five minutes. The egg will be nearly as smooth as custard, and is almost as easily digested as a raw one, while its flavor is something delicious.—*The Nightingale.*

Naregamia Alata, a small shrub with pendent branches and triple-pointed leaves, a native of Goa, is said to possess valuable expectorant properties. The plant is used in India by the natives as a remedy for biliousness, and is also given for the relief of dysentery and in catarrhal affections of the respiratory organs. The drug is exhibited in the form of a tincture extracted from the thin bark of the branches, the dose of which is from five to fifteen drops three times a day.

Suing the Wrong Party.—A young woman in Summit County, O., was supposed to be suffering from an ovarian tumor coming on, it was alleged, as a result of injuries sustained in a railroad accident. Her suit for damages was still pending against the railroad company when an operation was deemed imperative. The surgeon was somewhat surprised on opening the abdomen to discover a dead full-term fœtus. The railroad company now disclaims all responsibility for the tumor.

German Medical Diplomas.—In the numerous small free faculties of Germany the medical students pass their examinations in the following manner:

"Do you smoke?" asks the examiner.

"Yes, sir," answers the student. "Will you have a cigar?" (*Hands the professor a pfenning cabbage leaf cigar.*)

"Tell me," says the professor (*slowly lighting his weed*), "what are a physician's principal duties?"

"To collect his fees, increase his practice, and exhibit his diploma from the time-honored University of Guzzleburg," replies the student.

"Where shall you practise?" demands the professor, "and what are your duties toward me?"

"I shall go to America, among the ignorant natives, and make a golden harvest. And my duty toward you, Herr Professor, is to invite you to dinner for the rest of the semester," answers the student.

The professor smiles and says: "You are right. Let us go to a restaurant opposite and I will sign your diploma. The diplomas of the time-honored University of Guzzleburg are admired and respected in America. I have a cousin who is a doctor in Chicago. Let me tell you how the Indians chased him on Prairie Avenue. He was wounded twice by their arrows, and captured, but was released by his pursuers when they found on his person the time-honored diploma of the University of Guzzleburg. Ah! here's the restaurant, and I will make out your diploma from the time-honored University of Guzzleburg."—*Cincinnati Lancet-Clinic.*

NOTES ON THE REFLEX NEUROSES.[1]

By JOHN LORD BABCOCK, M.D.,

ITHACA, N. Y.

One day last week, I was called to treat an abscess in the hand of a young lady of about fifteen summers. While I was examining her hand she took a very lively interest in the proceeding, telling me very vivaciously how she had received the injury which caused the trouble. She was going on with the story very volubly when she saw me reach into my surgical case and procure a knife, pair of scissors, small forceps, and some absorbent cotton. I told her that I must open the little abscess at once. Her face immediately became all sicklied over with the pale cast of—nausea, and in about fifteen seconds she was at the verge of syncope, and vomiting profusely, and all this before I had touched the throbbing point with an instrument. This very simple, little every-day occurrence suggested three or four cases bearing on the rather threadbare subject of the reflex neuroses. Before I go on, perhaps we had better clear the ground a little by making two or three definitions. A neurosis has been defined as "a functional disturbance without any demonstrable organic change in the organ disturbed," and these manifestations must, of course, be clearly differentiated from organic disease on the one hand, and from pure hysteria on the other, with neither of which it has much in common. A physiological reflex action, such as the sudden withdrawal of the hand from contact with something very hot or very cold, or a flow of tears when we get a cinder in the eye, is a complicated process, involving, as we all know, at least six distinct steps and employing six organs. There is first, the nerve-end organ, which receives the impression; second, the afferent nerve; third, the centre in the spinal cord or brain in which the impression is received, and from which the reflex impulse proceeds; fourth, the efferent nerve carrying the impulse; fifth, the end-plates of the nerves in muscle or epithelium or corium which is excited on receiving the stimulus. This is the normal procedure, entirely out of will control, which saves us from injury a dozen times a week. It takes place when we are asleep as well as when we are awake, although not with the same rapidity or certainty. My reason for stating these simple and familiar facts in regard to normal reflex action, is to insist upon the importance of remembering that pathological reflex action manifesting itself in a neurosis, is the same sort of a process as the physiological, the difference being in degree, not in kind.

Somewhere among the six steps or parts of the action, the diseased condition manifests itself and modifies the result in point of intensity, location, or duration; but the process always retains the essential elements of the normal reflex act. Reflex neuroses are characterized by several qualities, each of which is related to one of the six steps or parts of the normal process. First, there is always a distinct indication of the local irritation which gives rise to the reflex nervous irritation. This indication may be misunderstood, or it may be overlooked, as is very often the case, but the causal trouble always manifests itself more or less positively. I do not believe that the irritable ovary that the gynecologists used to talk about ever produced severe headache as long as the woman's only consciousness of the existence of the ovary was a little pain suggested by the doctor and located in the region where the ovary is supposed to be, but where it never is; this pain being usually at the points where the nerves of the lumbar plexus pierce the fasciæ and become superficial. If "ovarian irritation" is going to produce reflex phenomena, it declares itself first by positive local symptoms of its own. So, too, with the teething of infants—that last resource to which we all betake ourselves when we don't know what on earth is the matter with the baby. We say its "teeth trouble it," when in reality there may be no local indication of any trouble whatever in the mouth. There is something mysteriously satisfactory in saying that the baby's teeth are the cause of about all of its ailments. The old ladies will all believe us, and perhaps we may almost believe ourselves; but the fact remains that unless you find congestion and tenderness in the infant's mouth, which conditions are rather rare, you ought to look further for the cause of the diarrhœa or constipation, and you ought not to satisfy the trusting parent by talking about the teeth. Reflex nervous troubles vary in intensity as the irritations which cause them vary, and there is a positive, unmistakable, and continuous relation between the two. When the causal disturbance is aggravated, the reflex phenomena are more pronounced.[1] A true reflex neurosis is usually sudden in onset, and if it takes the form of convulsions, they are severe and explosive in type. The reflex pain is usually acute, and, in my experience, has almost always been associated in the mind of the patient with the irritation causing it. Lastly and chiefly, the results of treatment in this class of cases are conclusive in reference to diagnosis. In fact, no diagnosis of a reflex neurosis can be considered substantiated until it has disappeared with the removal of its cause. Treatment directed to the reflex trouble itself is never of any permanent benefit, whereas, when the irritation which causes the neurosis is discovered and the treatment is directed to the removal of that cause, the results are almost magical. I think error is made by far too often on the side of laying too much to the charge of reflex irritation. It is, for example, such an easy, short cut to a diagnosis to tell a woman who eats and sleeps improperly who will not take the trouble to compel a normal movement of the bowels every day, and who will not dress properly, that she has "ovarian trouble." If you tell her in the right way, you win her everlasting friendship, for it is so much more interesting and pleasing to have "nervousness" from mysterious ovarian irritation than it is to be tired out by laziness, and poisoned by fecal absorption; and so the woman puts a little dab of iodine over the sigmoid flexure or the caput coli, takes two or three pills, and, of course, her "ovarian irritation" is temporarily very much improved. In this connection one might mention the worm-man; the doctor who attributes almost every ailment of childhood to intestinal irritation due to worms, those mysterious cave-dwellers of our economy that sometimes (not always) make childhood's hours so delightful. Of course, there are children who have intestinal parasites, but among people who use good water and properly cooked food, they are very rare. Let a doctor, however, once make up his mind that the symptoms of a case that

[1] Read before the Tompkins County Medical Society, at Ithaca, N. Y., March 26, 1890.

[1] See The Relation between Peripheral Irritation and Nervous Phenomena, by M. Allen Starr, in the Medical Record of January 4, 1890.

he does not clearly understand are due to worms, and that man is forever lost; round-worms, tape-worms, and thread worms will be the burden of his song to the end of his days. He will please the aunts and grandmothers, too, because the thing that enjoys the greatest popularity as a cause of children's diseases, next to teeth, is worms. I should hesitate to say just how many parents in Ithaca give their children "worm medicine" once a month, just on general principles. One of our professional brethren here, a few weeks ago, owned up to starting off almost every sick child he saw for the first time, on a good round dose of santonin and calomel, and I don't suppose he kills them all either, although I have not the slightest doubt in the world that his medication is usually wasted sweetness. In this connection I am reminded of a story that perhaps you have all heard, for it is so ancient that it was probably first told in Galen's back office, but it is to the point, so you must bear with me while I tell it. It seems that many years ago, there lived a doctor who modestly stated in his professional card, according to a new code which was enacted at about that time, "special attention given to diseases of children," and it was his invariable custom, on seeing a sick child for the first time, to look wise, say solemnly to the mother, "Worms, madam, worms!" and proceed to act accordingly, without any apparent reference to the condition of his patient.

He was called, one afternoon, to the house of a neighbor to see his child. He glanced at the little boy, and turning to the mother, remarked, "Worms, madam, worms!" and proceeded to prepare his usual anthelmintic. As soon as the boy's mother could get her breath she replied, "But, doctor, Tommy's leg is broke. He was climbing on the roof, and he stepped on a piece of rotten wood and it broke under him, and so he fell and broke his leg."

The doctor never stayed his hand. He said, "I told you so, madam! worms in the wood, madam! worms in the wood!" And so Tommy got his dose—and so the worm pathologist sees nothing in his practice but worms; while the gynecologist believes that "a woman has no organs outside of her pelvis;" and the oculo-neurologist cures headache, epilepsy, dyspepsia, chorea, insanity, and everything else except perhaps the itch, by rectifying the altogether too erratic and frisky eye-muscles.

The recent discussion in the New York Neurological Society, of the question of eye-strain in reference to reflex nervous diseases, at once suggests itself as bearing upon my subject. I cannot, of course, pretend to discuss that burning question at length; but I would like to relate one case which illustrates several of the points made above. The case is that of a boy aged about eleven, who has suffered about seven years from that form of epileptic seizure known as petit mal. About four years ago, attention was called to his eyes, on account of his evidently imperfect vision. There was also conjunctival trouble, photophobia, and the usual headache. A New York specialist examined his vision and prescribed glasses, which were used with most excellent results. An ointment was given to him at the same time for his blepharitis, after using which there was no further consciousness of eye-strain.

In November, 1887, muscular insufficiency was discovered in both eyes, and he was sent to one of those most highly specialized of specialists, an eye-strain neurologist, for treatment of the eye-muscles as a cure for his epilepsy.

Before this, the boy had been taking bromides very freely, was in a bad condition of general health, and was in a very much over-wrought, irritable state of mind. Like most specimens of the neurotic temperament, he is an extremely bright boy, and very impressionable. His seizures had been recurring at a quite regular interval of from three to four weeks at this time.

The eye-strain specialist examined the boy and detected several degrees of some sort of phoria—esophoria, I think. He proceeded to operate with quite positive assurances of curing the epilepsy. At the same time the doctor stopped all medication. The immediate effect of the operation, together with the withdrawal of the bromides, was very good. The boy's appetite improved, he began to sleep well, and high hopes were entertained of his recovery; but at about the usual time of the next month, his epileptic seizure recurred with about the usual force. It must be remembered, however, that they were almost always of a mild type. During the past two and a half years, our specialist has been making partial or complete tenotomies of the various eye-muscles from time to time, and on one occasion "advanced" one of the recti of both eyes, doing in all ten or eleven operations. The boy's general health has steadily improved, but his monthly attacks have regularly reappeared, with variable severity. The doctor has "corrected" esophoria, exophoria, and hyperphoria at different times, and now says that there remains some sort of strain, due I think, he says, to hyperphoria, which only needs to be corrected to effect a permanent cure. It is difficult to understand when the necessity for these little operations will be overcome. Every examination made by Dr. —— during these two years has developed some new deviation that demands immediate treatment. In this particular case, there must exist one of two conditions—either the epileptic seizures must be entirely independent of the eye muscular insufficiency, or if such inequality does exist as a cause, it is practically impossible to produce by operation an exact equilibrium among the eye-muscles. Beyond the eye-strain due to the myopia, which was corrected by glasses in the first instance, this boy's eyes have given him no trouble, so that if we accept the condition stated above, that a reflex neurosis cannot exist without consciousness of the irritation giving rise to it, we must conclude that this case verifies the conclusions of the committee of the New York Neurological Society, reported on November 5th last, that "the method" (referring to tenotomies practised on the eye-muscles with the view of curing epilepsy and chorea) "does not afford a sufficient degree of relief to patients suffering from chorea or epilepsy, to warrant its adoption or recommendation as a means of cure, or as a sole therapeutic measure," and therefore, as far as the scope of this paper is concerned, epilepsy and chorea are not to be classed among the eye-strain reflex neuroses.

Several years ago, I came in contact with a case which puzzled me a great deal. It came under my observation while my sign was yet bright and new, and being fresh from the medical college then, I was quite enthusiastic about the reflex neurosis. I was quite sure that my patient had ovarian irritation, which at that time was quite fashionable. She lived in an expensive boarding-house, and was very much afflicted with that most malarious sort of malaria which caused her to lie in bed late in the morning, and have her breakfast sent up to her room. She had awful headaches and backaches, and after she had had an unusually severe attack of her special sort of "malaria" and "ovarian trouble," she would develop the most terrific dyspnœa. She would kneel on the floor, supporting her shoulders on two chairs, and gasp for breath amid a circle of horrified and sympathetic friends and relatives. There was acute pain on pressure in the inguinal regions, and inasmuch as just at that time the gynecologists were beginning to remove ovaries for the cure of hystero-epilepsy, it struck me that here we had a somewhat allied case, *i.e.*, a true case of a reflex neurosis from a neuralgic ovary. The more treatment the woman received the more she liked it, and the more she wanted. At one time she had accumulated five different kinds of medicine, and was taking them all at once, besides making an external application twice a day. In the course of the next year her husband rented a house and departed from the boarding-house. As soon as the woman had work which she was obliged to do, and in which she was interested, her "nervousness," headache, backache, and attacks of dyspnœa disappeared. Her case was

not one of a reflex character at all. It was simply hysteria, bred of boarding-house idleness and a morbid desire for sympathy.

Having thus touched upon two cases which illustrate common conditions which are not reflex neuroses, I will relate the histories of three cases which are distinctly of that character, cases in which the reflex character of the trouble was positively demonstrated by the immediate and permanent relief which followed the removal of the cause in each case.

The first case to which I will call your attention is that of a woman, Mrs. M——, aged thirty-eight, who has one child of four years. She is of a distinctly neurotic type and inheritance. She came to me in October, 1887, complaining of an uncontrollable twitching of the muscles of the right leg, together with severe pain in the region of the sciatic nerve. I carefully inquired into the history of the case and found no tangible cause for these symptoms. Her appetite was good, she had a regular movement of the bowels every morning, and she added that her health was always excellent, except that when she was overworked and tired she became constipated, had terrible pains in the back with shortness of breath, and a peculiar "rash" which she described as breaking out in large spots on the upper part of the body. She had been free from this peculiar sequence of troubles for the past six months, although it usually recurred three or four times a year. She did not associate that trouble in any way with the sciatica and muscular irritability. I questioned her again as to the condition of the bowels and rectum, because I suspected some trouble there, but she answered very positively that there was no difficulty whatever with the bowels, and as she seemed to consider that subject one not to be discussed, I forthwith dropped it. Treatment directed to the nervous conditions presenting themselves, resulted, in the course of a week or two, in quite decided improvement, and I thought nothing more of the case until the afternoon of the following Christmas, when I was called to see her in a great hurry. I found her gasping for breath, pulse 140, temperature normal, and evidently in great pain. On the left shoulder was a somewhat raised, dark-reddish spot, about the size of the palm of one's hand. There was no special heat in the skin at that spot, and there was no white line following pressure with the finger. There was a similar, but smaller, patch of the erythema on the forehead. She then told me that the regularity of the bowels about which she had been so positive a few months before, was only produced by the daily use of a large enema of hot water, and that the ensuing movement was very painful whenever it was hard in character. It had been of that sort lately, and she said that she was sure that all of her symptoms came from the pain that followed such a movement. This pain was very intense, lasted two or three hours steadily, and then came on in a spasmodic way all the rest of the day. The character of the pain, of course, suggested fissure in ano, which on examination proved to be the lesion, together with a very large internal hæmorrhoid which came down upon the sphincter and irritated it. This, of course, is not an uncommon condition, but the case was peculiar on account of the extent and prominence of the reflex nervous phenomena. The sciatic neuralgia had returned in greater force than usual, there was most marked vaginismus, which was said to have been in existence since the birth of the child, four years ago. I at once advised an operation, but owing to a morbid dread of the anæsthetic, it was refused. All the changes were rung on the ointments, to no avail. Suppositories were inserted twice, with the result of making the patient faint with pain.

Chloral and bromides were given at night, and morphine was used hypodermatically, but all with only temporary result. The woman lay in great pain all day, with the hæmorrhoid pushing down on the sphincter and the sphincter contracting on the fissure. The erythema referred to above reappeared five times in a week and a half, on different portions of the upper part of the body. The localized redness lasted from five to eight hours, and was followed by a very fine, slight desquamation. The suffering from neuralgia in the left leg was intense, and a movement of the bowels occurring in the morning prostrated the woman for the whole of the day. She continuously lost strength, her appetite failed, and finally, in disgust at the way things were going, I told her husband that if he continued to refuse to allow me to operate, I should throw up the case. At that he reluctantly decided to let me go on, and so under ether I stretched the sphincter, cut the fissure, and removed the hæmorrhoid, proceeding in the ordinary way.

It required four weeks for the woman to recover from her exhaustion, and since then, it is now more than two years, she has enjoyed perfect health. She has had no attacks of dyspnœa, no hyperæmias of the skin, no vaginismus, no sciatica, and back of all these improvements, no irritation in the rectum and anus. This case was peculiar on account of the intensity of the reflexes and the peculiar character of the hyperæmia referred to. If the simple little operation had been performed several years ago, it would have saved the woman a great deal of trouble. Another patient illustrating a rather similar type of case is that of Mrs. N——, aged sixty-five, who presented all the symptoms of ulcer or fissure of the anus, together with a burning pain on passing urine. Examination showed no anal or rectal trouble whatever. The urethra seemed normal; there was laxity of the vaginal walls that was to be looked for in a woman at her age, and there was a slight retroversion of the atrophied uterus. For this a large Albert Smith pessary had been applied, but, as is often the case with pessaries, it had increased the irritability of the rectum besides making painful pressure at the neck of the bladder. She had been treated with demulcents and alkalies for the burning on urination, but they had done no good. Numberless local applications had also been made in the rectum, but without avail. I first saw the patient in November, 1888. She called me in to remove the pessary referred to, which had become intolerably painful. I examined a specimen of the urine and found it alkaline, but otherwise normal.

The condition at once suggested anal fissure, irritable ulcer or hæmorrhoids, but I could find nothing about the rectum or in it that seemed to have any bearing on the case. The pain accompanying and following defecation, together with the scalding of the urine and tenesmus of the bladder, had remained about the same for six months, and the woman was beginning to show the wear and nervous strain of the thing. I have a little speculum designed for the nose, which I have modified a little and used for urethral dilatation. By its use one can see the outer half or three-fourths of an inch of the urethra very well. I passed it into the urethra in this case, and you may imagine my surprise on seeing a large urethral caruncle, crowding up between the blades of the little instrument, about half an inch within the canal. It was fiery-red in color, bled easily on being touched, and was exquisitely tender. I inserted a pledget of absorbent cotton soaked in a five per cent. solution of cocaine into the canal, and presently was able to cut away and remove the little tumor. After five or six days, when the little pedicle had healed and the irritation subsided, the woman found that all of her distressing rectal symptoms had disappeared. These symptoms in the case were of a purely reflex type, and it is not difficult to understand the connections between them and the causal irritation in this case, nor the spasm and vaginismus in the first case; for the urethral orifice and the anus are supplied by terminal filaments of the same nerve, the pudic, and it is a well-known fact that irritations at one point in the distribution of a nerve often produce reflex irritations at other points in the distribution of the same nerve. It is not so easy to explain the circumscribed hyperæmias in the first case referred to. They were presumably due to a vaso-motor paralysis, but why they should occur only on the upper part of the body, and what the indirect connections are between the

pain of a fissure in ano and the circulation in the areas referred to, are questions difficult to answer. The prompt disappearance of all the symptoms in both cases, as I have said, fully verified the diagnosis. The last case to which I wish to call your attention is of a distinctly different type. It is that of T. B——, aged seventeen. This boy was a homeless tramp, who had drifted away from the coal mines of Eastern Pennsylvania in which he had been working ever since he was nine years of age. He had been picked up in the street by the ambulance and brought to the hospital of which I was an interne at that time. The ambulance surgeon reported that he had found him in some sort of a fit. He was anæmic and emaciated, and undeveloped for his age.

Examination revealed nothing abnormal in the chest except an anæmic bruit with the first sound of the heart. His temperature and respiration were normal, and his pulse somewhat accelerated. He said that he had jumped on a coal train at Scranton, three days before, and had come down to Hoboken, but he did not remember much of anything else since his arrival there. The first and plainest indication in his case was that he needed feeding, and it seemed that the lack of food was his principal trouble.

He said, however, that for the last six months he had had "awful bad" headaches once in a while, with dizziness and a very bad feeling in his stomach. His exhaustion and starvation were very soon overcome by a milk diet. Two or three days after his admission he complained of the pain in the head. He had marked vertigo, so that he fell on trying to walk across the ward. The headache was of the burning, throbbing variety, and very severe. He was a very dull, ignorant youngster, of the lymphatic temperament, and the reality and severity of his pain were beyond question. Before and during these attacks of headache and vertigo, he always complained of a sensation in his stomach which he described as being as if he had a piece of coal there, and he frequently had a sudden excruciating pain through the abdomen which he could not locate very definitely.

During the attacks of vertigo and headache his pupils were sometimes very much dilated, usually being unequally so. These attacks were sometimes so severe that he became unconscious and had slight convulsive movements resembling seizures of petit mal. The case was obviously very obscure, and after his visiting physician had given him large doses of bromide for two weeks, to no effect at all except that the treatment made his general condition rather worse, he called a consultation of the medical staff of the hospital. Those were the days when I thought that most of the medical and surgical wisdom on earth was concentrated in our hospital staff, and I looked forward to this great combination of diagnostic skill as the only thing necessary to settle the vexed question. But alas! I did not then know as much about doctors in general, and hospital doctors in particular, as I later learned by sad experience—and I am sorry to say that of course they disagreed. One of them said it was gastric neuralgia, or beginning ulceration; another, an enthusiastic neurologist, said that the attacks were probably epileptic in character, that the real trouble was in the brain, and that the stomach symptoms were simply incidental and of no real consequence. As a result of the consultation, it was decided to put the lad on medium doses of iodide of potash, and to control the pain with morphine. Under the alterative treatment, his general condition certainly improved and the morphine gave him temporary relief, but his condition as to the recurrence of the lancinating pain in the head, and the "piece of hard coal" and peculiar pain in the stomach remained the same. His appetite remained good, although his dose of morphine was gradually increased, and there was a steady constitutional improvement. His bowels were regular throughout; and so the case went on until one memorable day in April, when our superintendent decided to give the patients who were on "g. w. d." (general ward diet) some salt mackerel for breakfast. They had been purchased at a bargain, especially for the hospital, and were doubtless "real cheap." Now, something had happened to those fish, and they had acquired that peculiarly rich, gamey, and aromatic odor, having which they are commonly described as being "sprung." After breakfast we started to make morning rounds, and were met on all sides with doleful tales of "throwin' up," and "heavin' off," due to over-flavored fish. About two-thirds of those who had eaten the mackerel had vomited, and they were all deeply grieved, but when we reached our young patient's bedside, we found him smiling as broadly as he could between his emetic successes. He looked up at us as we came along, and pointing to a basin on a chair near his bed, said: "There's them fits!" We looked into the basin and there we saw two very healthy, actively squirming, and unusually large, round worms. He was right—the basin contained his vertigo, headache, petit mal, gastric neuralgia, gastric ulcer, and all; all were there, represented in the activities of those two worms. The boy's recovery was instantaneous and complete, and he lived to steal twelve dollars from one of the nurses and get away with it; but nevertheless, I do not advise the addition of stale fish to the therapeutic resources of general hospitals.

SYPHILIS IN JAPAN.

By ALBERT S. ASHMEAD, M.D.,

NEW YORK.

Much of the prostitution of Japan is licensed. In the larger cities this is so, and in various provinces. In the former it is the usual custom to set aside allotted sections for this purpose, and, cunningly, in most instances, on the direct way to and near some celebrated and popular Buddhist or Shintoō shrine, or other attractive place for the multitude. In the city of Tokio the prostitutes' quarter was upon the road to and near the Temple of Asakusa, the largest and most popular of all the temples in that city, and which still preserved, in declining glory, its celebrated wooden health-god, to which Buddhist superstition attributes mythical medical power to heal the sick and deliver from pain. It was nearly obliterated, however, through the Buddhist "rule of treatment" requiring the part of the image corresponding to the affected part of the believer to be gently rubbed, while prayers were offered to his majesty and money thrown into the "capacious jaws" of his treasure-box, this venerable superstition being a remaining legacy from olden medical priesthood.

A peculiarity of Japanese prostitution is the surprising fact that it entails no dishonor or disgrace subsequently on its "divinities." A woman because she has at some time occupied this "enviable" position is in no way curtailed in her marriage availability. She may afterward form a union without social stain or ostracism, it being reasoned that a "social evil" is necessary in a nation of men and women, and that what contributes most to the happiness of the multitude is wisest in their day and generation. And probably, too, that in a country whose maximum of population has at one time or another contracted syphilis—or escaped it simply because of ancestral protective inheritance through multiple inoculations in preceding generations—no Puritanical or prudish rule should prevent the frank acknowledgment of things just as they are.

A distinguishing style of dress was obligatory upon women of this class, so that persons meeting them might readily perceive their calling. This insured "old maidens" from various possible dangers, while it protected respectable married women much better than their hideous custom of blackening the teeth, etc. It will be just as well to mention here that the purity of domestic life in Japan is not identical with our idea of what should constitute it. I do not mean to intimate that the women of Japan are not virtuous, for they are, but the wife lives

with her husband and children in the same household with his concubines.

Concubinage was general under the older Japanese *régime* before the new order of civilization under the present wise Emperor Mitsuhito, who began his newer government in 1867.

Children of concubines are legitimate, although bearing different surnames. It was not unusual to see a wife and four concubines living in peace, harmony, and seeming contentment under the same marital roof. We have the saying that "no house will suffice to hold two mistresses." I do not know if there is an equivalent expression in the Japanese vernacular, but suppose there must be some limitation to such a "state of things," other than a physical one. I have seen for myself five concubines with a "wife," all living in the same fold; and the lord of this "flock" was my friend, and a particularly fine fellow, without vice—an agreeable gentleman. I have no doubt that he was equally agreeable in his own household. I know that his "numerous choice" of the "fairer sex" were delightful and pretty women, sufficiently so to attract and charm most any one; and, at least so far as I could perceive, no green-eyed monster was alive among them. The Japanese wife, complaisant usually under the prevailing arrangement, is both pure and good, and is equally kind to all the various progenies of her master.

This household arrangement of the Japanese civilization is decidedly "Schopenhauerish;" it would have delighted that radical philosopher and given him fresh pabulum for a new theme.

The medical supervision, control, and direction of this prostitute question in Tokio was a part of my professional service in Japan. With an able corps of sixteen native physicians, regular weekly visitation and examination of these women was made, and those who were found to be diseased were brought to the hospital *lock* wards for treatment, where they were placed in separate rooms according to their types of disease, from four to twenty in a room. On certification of cure they were afterward relicensed by the Government.

The prostitute tax tribute of Tokio amounted to a considerable sum, as there were some two thousand licenses issued, each prostitute paying a tax of two dollars a month, each licensed restaurant or tea-house proprietor who did business in the "prostitute quarter" paying a tax of three dollars a month, and the house-owners themselves, who derived the largest share of profit from the occupation, paying the highest tax of all, viz., five dollars a month, all of which revenue reverted to the hospital. The law forbade public exhibitions of the women of this class at their windows and doors, excepting at stated hours in the early evening. Most of the prostitutes were able to speak many words of foreign languages, their attractions evidently having conquered different European hearts.

A vast amount of venereal disease, in this service, and in that of the regular "in" and "out-door" departments of the hospital, presented itself for treatment. I suppose there were fully ten thousand cases in all, from ten to twenty a day, anyhow, the various forms of syphilis and its sequelæ, being pre-eminent. Primary sores were Hunterian and chancroidal—the latter, in my experience, proving non-infecting, and not the contrary, as was curiously claimed for Japanese chancroids by Dr. Simmons. I have auto inoculated chancroids in Japan and every time have produced a sore. Auto-inoculability of Japanese multiple chancroids is constant; auto-inoculability of Japanese unique chancres is not possible. Phagedæna is rare. I have seen it, however, and very virulent gangrenous types of it, but only in the lower classes and in the underfed. Syphilitic adenitis and lipoma are wonderfuly prevalent.

Sloughing in the Japanese is easily induced, probably from their not having had a meat dietary for ages, it being prohibited in the sixth century. I found it not difficult to exsect by suppuration initial lymphatic non-softening infections; the glands would readily loosen and discharge; bichloride of mercury saturations after a blister, with poulticing for thirty-six hours, accomplishing the result. And here let me note that the relative absence of scrofula in Japan is surprising. One would naturally expect to find in so syphilitic a country an extraordinary amount of it, but this is not the case. It is rare to meet with it.

Dr. D. G. Brinton, of Philadelphia, recently suggested that to my ethnological study of phthisis, syphilis, and leprosy of Japan—I should add a fourth disease of allied disorder—namely scrofula. Much to his surprise, I judge it must have been, I wrote him that the disease was not entitled to much consideration in this relation through its relative infrequency. This statement of mine regarding scrofulosis in Japan is corroborated by Dr. Simmons in one of his more recent articles in the MEDICAL RECORD.

There may be some connection between its marked absence and the mildness or abortive character of tertiary syphilitic symptoms. I have known children of late-syphilitic-manifestation parentage (who were born late in the life of the parent) to show so-called scrofulous symptoms. One American case in particular I recall, that of a Mississippi steamboat pilot, in whom syphilitic appearances developed twenty-six years after the primary sore, and one of whose children, aged five years at the time of the parental manifestation of the disease, showed specific scoliosis, and was treated by Dr. Gibney of this city. Another child (twelve years old) showed the regular glandular enlargements. The elder Dr. Gross, in his clinic, used to say that scrofulous (?) bone disease was often merely modified generational syphilis.

The father of the two children mentioned had, as late manifestations, palmar and solar syphilitic psoriasis with ulcerations, and syphilitic hypertrophy and afterward atrophy of liver.

Syphilides in Japan are papular, squamous, and pustular. Tubercular syphilides are rare, possibly because of their being rather the connecting link between the secondary and tertiary forms of the disease; the latter being abortive, they are absent.

Syphilitic iritis and choroido-iritis are frequent. Cock's-comb condylomata and infecting warts are plentiful, both of the genitals and anus. In women they are more common still, large bunches of them, the size of a fœtal head, often showing themselves in the out-door clinic. When we consider the universal custom of public hot bathing, without proper medical supervision or restraint, is it at all wonderful that venereal warts abound?

Secondary syphilis presents features in no way different from those of our disease here.

Ulceration of mucous membranes is sometimes troublesome to check, but mostly amenable to bichloride washes. And here again, let me say, that sublimate treatment of various diseases in Japan is as old as their ancient Chinese civilization. We can learn from them many of its uses. I believe that the old "Dosia powder" story told by Mr. Titsingh, an early writer on Japan, in his "Mémoires et Anecdotes sous la Dynastie Régnante des Dfogouns Souverains du Japon," in relation to the Japanese production of flexibility in corpses after "rigor mortis" has set in, was not entirely a myth. I rather infer the white sand-like powder used in stuffing the various natural outlets of the body, nose, ears, mouth, etc., to have been simply bichloride of mercury. And it was probably used to sanitarily counteract putrefaction.

Dr. Koempfer, the early Dutch physician and writer, reports in his work, published in London in 1727 A.D., that quicksilver and sublimate of mercury both were imported into Japan from China.

Specific ozæna, with destruction of the nasal septum, is quite common, permanganate of potash being the local remedy relied upon to abort it.

I record one case of parietal bone tertiary syphilis, which was in a young woman, not a prostitute, resulting in considerable loss of bone vault, but which yielded to

heroic iodide treatment, finally recovering and passing out.

Tertiary forms of osteitis are met with, but not as frequently as in European syphilis. I agree with Dr. Simmons's and Dr. Eldridge's statements as to early limitation and subjection of the disease. Much necrosis of shaft bones is met with, but by no means always of syphilitic origin.

Caries of the vertebræ I found to be abundant, with consequent psoas or other abscesses requiring surgical procedure. Digital destructive disease of bone in Japan is mostly leprous. Hypertrophied induration of the tongue is frequently seen, supposed to be of tubercular (?) origin; it is not ulcerative.

Syphilitic valvular disease of the heart is common, in fact the cartilaginous system generally suffers much more, I think, than the bony system.

Destructive suppurative disease of the testicle, usually the right one, not cancerous, but supposed to be tubercular (?), is largely prevalent—at least, it has so shown itself in my service. It might possibly be of sarcocelatous nature. Here let me say that tubercular and syphilitic diseases in Japan are strangely interwoven, they are not nearly as clearly defined in their nature as leprosy. The diagnosis of the former two is many times a puzzle, the two diseases being intertwined clinically in a peculiar way.

Hydrocele is also very prevalent, perhaps due to injury from the barbarous and universal use of the breech-clout, or from the weakening influence of daily hot bathing.

All tertiary forms of syphilis are tractable and quickly yield to treatment.

Syphilitic paralyses are difficult to define, owing to the frequent existence of Kakké neuritis. They are not thought to be so common as with us. Spina bifida is frequent.

The introduction of vaccination was not of importance, relatively, in the multiplication of Japanese syphilis, through occurrence of inter-inoculation.

"Vaccination was first introduced into Japan at Matsumai in the Island of Yezo, from Russia, by a Japanese fisherman in A.D. 1824" (Dr. Whitney). The Island of Yezo is the home of the peculiar aborigines of Japan, the Ainos, who gave to that country their practice of tattooing. Tattooing is supposed to have originated acupuncture.

"Vaccine virus was introduced to Nagasaki, which is on the island of Japan proper, by Dr. Mohnike, a Dutch physician, twenty-five years later than in Yezo, viz., in A.D. 1849" (Dr. Whitney).

"Inoculation was first practised in China before the ninth century; but small-pox was known in China before the second century" (Dr. Wylie).

"First epidemic of small-pox in Japan, A.D. 735" (Dr. Whitney).

First written work on syphilis is supposed to have been written or published in A.D. 809.

The practice of acupuncture must surely have propagated much small-pox and syphilis in Japan through inoculation!

"The 'tube acupuncture needle' was invented in A.D. 1688" (Dr. Hepburn).

"Rise of the school of Yoshimasu Tamenori, which held all diseases to be due to one specific poison, and that treatment should consist in neutralizing this poison by another poison equally powerful—a kind of homœopathy! A.D. 1751–1763" (Dr. Whitney).

Rather a dangerous belief in a syphilitic and leprous and acupuncture country! I have vaccinated lepers and children of lepers, without noticeable difference. I have auto-inoculated lepers without result, so far as I had opportunity of ascertaining.

"Vaccination was introduced at Canton, China, by Dr. Pearson, before A.D. 1805" (Dr. Wylie).

"An Institute of Vaccination in Japan was established in A.D. 1858. This was the foundation of the modern Medical Department of the University of Tokio" (Dr. Whitney).

Vaccination was made compulsory in Japan in 1874. This was the year of an epidemic of small-pox in Tokio, in which I was professionally engaged. In consequence of this compulsory law, from two hundred to six hundred vaccinations were performed daily, three days in the week at the Tokiofu Hospital, the system pursued being to have twenty diamond-shaped lances armed with virus ready, on a round table for the operator. The patients were brought up with arms bared, and rapid subcutaneous insertions were made, the lances being afterward washed, disinfected, and re-armed for the next batch of patients. Rarely were arm-to-arm inoculations performed. The virus used was the German importation in glass tubes. But few failures resulted and no bad effects, so far as syphilis was concerned, ever showed up. For two months these vaccinations were very considerable, gradually declining, from decrease in the number of presenting applicants. No thorough house-to-house vaccination could be made. Some was done, however, but the main vaccination occurred in the hospital.

I am sorry not to have statistics to present. Statistics in Japan are apt to be modified in the interest of some particular influence, and therefore rarely accurate.

The first Japanese gold was found and melted in A.D. 749; Japanese silver was found in A.D. 674, preceding the discovery of gold. Mercury must surely have been known to the Japanese, in their refinement of gold, at this early period, for gold was known in China from earliest times, and the Japanese would certainly have learned its refinement through the Coreans.

Dr. Simmons in THE MEDICAL RECORD, vol. xix., 1881, says as follows: "Syphilis (in Japan) is very prevalent, so much so that we think we are safe in saying that three-fourths of the male population, especially in large towns, suffer from it sooner or later. Our observations have led us to the opinion, however, that its manifestations are less severe than among the Europeans. Thus, with the universal opportunity which we have had of seeing the disease, we have found the secondary lesions as affecting the mucous membranes, in most cases, very transient and often wanting. Caries of the bones and other manifestations we also regard as relatively infrequent. The fact that, in former times at least, every case of primary syphilis was treated by thorough mercurialization may account for the mildness of the tertiary lesions mentioned." To this explanation of Dr. Simmons may be added that their habit of eating so plentifully of iodized sea-weed—a Japanese universal article of diet, would also be an influential cause of its mildness. Dr. Simmons also says as follows: "We may mention in this connection that it is a popular opinion in Japan that small-pox is much more severe in its national form, in those whose parents had never had the disease, or who had been prevented from having it by vaccination. Even if our observation as to the mild type of syphilis in Japan be correct, it is impossible to believe that its effect on the whole people is not profound, and serves to explain in some degree the generally admitted fact of the physical inferiority of the race, as compared with Europeans, and also the relative slow increase of the population thus favorably situated, during the last two hundred years."

I would add to these accurate observations of Dr. Simmons that the Japanese habit of persistent hot bathing may have had a good deal to do with their resistance to the destructive influence of the disease. Also, that for centuries back they have been conversant with the value of dry mercurial baths (burning cinnabar — binoxide or sublimate—under a canopy). They have also used in venereal throat affections inhalations of mercurial vapors.

What a Japanese or Chinese adept does not know of the beneficial venereal uses of mercury we Europeans certainly cannot teach him. There is one of its uses in general medicine not known to him and that is gynecological antisepsis. There is no puerperal fever in Japan,

nor scarlet fever, two diseases of mutual absentive significance. I record it that I have never seen a single case of either in Japan. I was told, however, that scarlet fever did exist, and that it was quickly fatal. I doubt it; for its presence would imply the presence of puerperal septicæmia, and this is absent. There is no gelding of horses in Japan, which may have an effect on eczema or distemper of the young horse, and this may have something to do with the absence of scarlet fever.

Fortunate women of Japan, to have escaped bichloride tablets! Perhaps an explanation of the absence of puerperal fever might be found in their exclusive midwife delivery of children. The solitary parturient woman, in a stooping-sitting posture, "bears down" on cords suspended directly above her, the midwife expressing downward with both hands on the patient's abdomen.

Diphtheria is also absent, and this fact, too, has a significant relevancy to the non-existence in Japan of puerperal fever. Mercury was puerperally and surgically unknown to Japan for antiseptic or aseptic purposes, though introduced perhaps in later years. Their surgery is only secondary. In this connection let me say that the country has for ages been without milk in its dietary. Milk and butter have never been used in Japan. The babies of this nation are not "bottle-fed," rarely artificially fed. Should necessity demand it, they are given thin rice-water or mother-chewed rice-cake. These are the "baby-foods" of Japan. Their women nurse their offspring and rarely wean them, sometimes having three children of different ages at the breast. The breasts of many of them never rest from secreting milk. Mastitis is frequent, but cancer of the breast is rare. I did not meet with one case.

Hart, of London, tabulated a review of seventy-one epidemics that had been attributed to infected milk. Three diseases he recognized as being so propagated: Typhoid fever, from the milk being adulterated with germinal well water (typhoid fever is abundant in Japan, yet they have no milk, and drink only boiled water flavored with tea-leaf), diphtheria, not clearly definable as to the mode, and scarlet fever, from persons about the dairy, who take care, at the same time, of persons ill of scarlatina, and the branny dust of the disease finding access to the milk.[1] All of which is very interesting in connection with the joint absence of scarlet fever, diphtheria, and milk diet from Japan.

Dr. Stuart Eldridge, of the Yokohama General Hospital, in the *Pacific Medical and Surgical Journal*, vol. xxiv., October, 1881, says as follows, regarding syphilis in the native of Japan: "It is almost commensurate with human life itself; all ranks of society suffer and probably in proportion far more nearly equal than in most other countries. It is very rare to find a male Japanese who will not acknowledge that at some time he has suffered with syphilis, while the general distribution of the disease, with the fact that little or no shame or disgrace attaches to the possessor of a venereal taint, renders its recognition by the people a matter of certainty and gives credibility to their statements in reference to personal experiences of its results." And farther on he says as follows: "The disease is benign." Also, "In this connection it would be interesting to take up the question of the convertibility of syphilis into other diseases, *e.g.*, scrofula; strong evidence against such convertibility can be obtained in Japan." As to the causes of syphilis Dr. Eldridge says: "They are prevalence of immorality, as with other Asiatics, and absence of fear as to consequences or anxiety, which leads to carelessness as to exposure or prevention. Syphilis having run riot in Japan for centuries, has to a certain extent worked its own cure, whether due to a gradual weakening or attenuation of virus or, as I am inclined to believe, to an insensibility to its action, the result of a universal taint, it is at present impossible to say." Dr. Eldridge believes that "its virus has become modified, because the blood of the natives through inheritance has become more or less infected, and so contagion is modified." Which is not at variance with pathology.

"It seems that in Japan we have only an exceptional progress in that amelioration of syphilis which has been going on, though not so rapidly, in other and better-known countries. That we rarely meet at the present day in Europe and America with the fatal and loathsome malady known to our ancestors as syphilis is generally acknowledged, while of syphilographers the younger school seem to rival each other in painting, not the horrors, incurability, and mortality of the disease, but its benignity, docility, and altogether trifling character." To all of which I cheerfully subscribe.

I believe in the Japanese developmental theory of disease, that diseases germinate or become modified by surrounding conditions. How can we explain the development of pulmonary tuberculosis, so often following acute syphilis? Generations of disease, too, may "vaccinate" a nation's blood. A disease that is non-auto-inoculable may give to a succeeding generation, not only its own specific inheritance, but a measure of resistance as well. The child of leprous parentage may not give to its children the same legacy that it received. What inference may be drawn, too, from the fact of "malignant leprosy" having preceded "galloping syphilis" in Europe. "Malignant leprosy," according to Michael Scott, "De Procreatione Hominis Physionomiæ," A.D. 1250, was contracted by sexual intercourse with lepers, a constitutional disease was produced by intercourse with a "leprous" woman, which disease was preceded by a penile ulcer.[1]

Dr. Kiernan also avers that "similar statements were made by various earlier writers," and "that 'galloping syphilis' originated in Spain A.D. 1484."

Between Portuguese leprosy and Spanish syphilis, and their relation to Moorish conquest, and the evident inability of earlier European writers to properly define a difference between the two diseases, and the simultaneous presence in Japan, from ancient times, of syphilis and leprosy, with determining gradual amelioration in type of the former, through evident inherited national resistance, there is a broad field for study.

Dr. D. G. Brinton writes me as follows: "The origin of syphilis is still an open question. It seems to me probable that it existed time out of mind in both the new and old worlds, but assumed a peculiarly malignant form in Europe at the close of the fifteenth century. Certainly, in America, syphilis of the bony system existed before the discovery, as is shown by the relics in ancient graves. Just at present Dr. Brühl, of Cincinnati, and Dr. H. N. Clarke, of Chicago, are making special studies on this point.

In conclusion, I will merely add that, in order to trace the analogy, I have written to friends in Japan to obtain, if possible, bones of lepers and syphilitics from the ancient graves of their older cemeteries. Whether the attempt will succeed or not it is difficult to say, as ancestor-worship of Confucianism is still in vogue among the baser classes, to which all lepers, at least, belong.

4 KING STREET, NEW YORK.

[1] New York MEDICAL RECORD, vol. xxi., 1882.

Fracture of a Rib from Coughing.—Mr. E. C. Masser reports in the *British Medical Journal* for April 26, 1890, the case of a man, aged fifty-four, who was suffering from bronchitis and Bright's disease. One evening he sent for the reporter, saying that he had great pain in his side. Upon inquiry it was ascertained that during a violent fit of coughing he had heard a snap, and had since felt a sharp pain in the same spot. Examination revealed the presence of a fracture of the rib. This healed as readily as could be expected in a man with bronchitis, and there were no signs pointing to any previous disease of the rib which would render it specially brittle.

THREE CASES OF ACUTE, PAINLESS, DRY PLEURISY, WITH REMARKS ON THE PHYSICAL SIGNS AND PROGNOSIS OF THE DISEASE.[1]

By R. VAN SANTVOORD, M.D.,

NEW YORK.

THE first case that I desire to bring to your attention is that of a boy, aged eleven, whose previous health had been good, except for nervous symptoms due to ocular defects. His illness dated from a chill, caused apparently by exposure. This was followed by cough, slight, but not constant, elevation of temperature, and general depression out of proportion to any manifest disease. Moist, superficial subcrepitant sounds were heard along the anterior border of the left upper lobe a week after the chill, cough with slight expectoration continuing. The superficial subcrepitant sounds extended finally over almost the whole surface of the left lung. For several days they were always present at every examination, and then gradually disappeared in about two weeks from their first appearance. During this time no pain whatever was felt. No morbid sound whatever was heard over the right lung, except an occasional coarse rhoncus. Toward the latter part of the case a slight feeling of traction was felt by the patient on deep breathing.

The patient made a complete and speedy recovery under rest, moderate counter-irritation, and tonics, mainly.

The second case was that of a man about forty-five years of age, with a florid complexion, rather stout, and disinclined to take much exercise. He had a short time previously suffered from an attack of influenza during the late epidemic, went back to business, and had to lay up again, suffering from a severe cough without much expectoration, much prostration, slight elevation of temperature, and neuralgia of one supra-orbital nerve, a complaint to which he had long been subject. Physical examination showed superficial subcrepitation over the lower right lobe. There was no dulness appreciable. There was absolutely no pain on breathing or coughing, only the patient said that his cough "came from his right side." Under quinine and arsenic, with occasional doses of phenacetin, and very small doses of aconitia for his neuralgia, the patient was entirely convalescent in two weeks, slight subcrepitation still existing when, owing to his complete recovery as far as subjective symptoms were concerned, he was allowed to pass from under observation. His urine was normal.

My third case was that of a lady approaching middle life. She had been subject for some years to cough with expectoration, and had gradually become considerably emaciated. She was seized with very intense dyspnœa during the night, having had a chill during the previous day. It was during this attack that I first saw her. The pulse was rather feeble. Weak emphysematous respiration was present over the whole right lung. At the left apex there was dulness and hollow breathing, which persisted after convalescence from her acute trouble, and was evidently due to an old lesion. Over the whole of the left lung was to be heard superficial subcrepitation. She passed 610 c.c. of acid, turbid urine in twenty-four hours, containing albumin, which formed a bulk of ten per cent. on depositing, urea about nineteen grammes, and numerous hyaline and granular and a few epithelial casts. Its specific gravity was 1.022. The subcrepitant sounds followed the same course as in the two preceding cases. The dyspnœa was intense and agonizing for some days. Neither pleuritic pain nor effusion that could be recognized followed. In spite of an extremely unfavorable prognosis given by a prominent consultant, she gradually regained strength, the slight fever from which she had been suffering and the subcrepitation disappeared; her urine became normal, and she has returned to her occupation as a school-teacher in a tolerably comfortable condition. Cardiac tonics and Basham's mixture were the main therapeutic agents used. Cough and expectoration, she thinks, is less than before the acute attack, but she suffers considerably from dyspnœa. Owing to an almost morbid sensitiveness about having her case investigated, I was not able to obtain a specimen of her sputum for examination.

The first point of interest about this little group of cases is the latency of their course as far as subjective symptoms of pleurisy were concerned, though all suffered more or less from cough. A second point is that in none of them, though repeatedly and carefully examined, did there ever occur a rough friction-sound. In all, the only physical sign was a subcrepitation, not distinguishable in quality of sound from an intra-pulmonary râle. In fact, in two of the cases I regarded the sounds at first as intra-pulmonary. As they extended, however, their pleuritic origin became evident from their superficial character, the fact that extensive areas of a single lung was in each case involved, and the constant presence of the sounds day after day in the same place. Had they been due to bronchial râles they would have been bilateral, inconstant, and affected by cough. All systematic writers call attention to the fact that pleurisies occur without characteristic symptoms, and probably sometimes without physical signs. In practice, however, I am inclined to think that inflammation of the pleura is not likely to be thought of unless it is suggested by pain or extensive effusion. This is particularly apt to be the case when the physical indication of the lesion is not a rough, grating murmur, which cannot be readily misinterpreted, but is, as in the above cases, not distinguishable in quality from intra-pulmonary sounds. The possibility that râles, coarse and fine, may be of pleuritic origin was recognized by Walsh,[2] in 1842. This is to day, I suppose, recognized by all authorities, Dr. J. R. Leaming, of this city, going so far as to teach that almost all râles are of pleuritic origin, a position which can hardly be recognized as conformable with what seem to be facts to most observers. It has seemed to me, however, from my own observation and intercourse with hospital internes particularly, who are fresh from the schools, that sufficient stress is not laid on this subject in teaching. Fourteen years ago I had an opportunity of watching the persistence of a crepitant râle in a case of pneumonia through every stage of the disease, and of hearing it still when the patient was discharged convalescent. This convinced me that, as Dr. Leaming teaches, the crepitant râle of pneumonia was a pleuritic sound, in that case at least, as its persistence through the varying stages, from consolidation to complete resolution of the pulmonary exudation, was not conceivable on the theory of its production in the alveolæ. The crepitant sounds heard at the apex in early phthisical consolidation are usually spoken of as râles indicative of local bronchitis. To Dr. Leaming and, if I am not mistaken, to Dr. A. L. Loomis, they are indicative of pleuritic exudation. In these two instances the question of interpretation is of theoretical interest only. In cases such as I have above cited, however, the distinction between pleuritic and intrapulmonary sounds is of primary importance in diagnosis.

I next desire to say a few words in connection with the above cases concerning the etiology and prognosis of diseases of the pleura. It is customary to divide pleurisies etiologically into primary, or those which arise apparently from causes acting exclusively on the pleura, the pleurisy being the main disease, and secondary, or those which occur as a local manifestation of a general disease or from the extension outward of some lesion of the pulmonary parenchyma. In the case of the peritoneum, as knowledge has extended primary or idiopathic inflammation has about disappeared from our nosology. In a case of peritonitis not due to direct traumatism we look for some general disease or infection of which it is a local manifestation, or a lesion of some pelvic or abdominal viscus

[1] Read before the Harlem Medical Association, April 2, 1890.

[2] Diseases of Lungs and Heart, second edition, p. 126.

of which it is the extension. The same mental attitude ought to be assumed in all inflammations of the pleura, although much still remains to be discovered in this field. In a recent analysis of 163 cases of pleurisy, apparently primary, occurring in the Zurich clinic in the course of ten years, Engsten [1] found 71 in which no known cause could be found. In 22 cases there was phthisis in the family. In 31 cases exposure to cold was given as the cause, 29 of them being pleurisy with effusion and 2 only dry. In many of these cases the pleurisy followed a few hours after a definite exposure to chill. Four cases were attributed to over-exertion, 1 to injury without recognizable lesion of ribs or skin, 16 had pneumonia, and 17 pleurisy on previous occasions, 2 occurred in childbed. An attempt is made by the author to show that these cases occurred in groups and to deduct from that fact the probable infectious origin of the cases, but his figures are too small to be very convincing. The thought occurred to me very strongly in the first case above narrated, viz., that of the boy of eleven, that the general depression of the patient was altogether out of proportion to the local disease, and that I was really dealing with a general disease of unknown nature of which the pleurisy was a local manifestation. In the second case, viz., that following influenza, the prostration was of course readily accounted for. Whether or not the pleurisy was a local manifestation of the disease or an intercurrent complication due to some other cause I am not prepared to say. The third case, viz., that of the lady with a history of cough and emaciation, with a vomica in one lung, and with albumin and casts in the urine, at first sight pulmonary tuberculosis, the often accompanying chronic nephritis and a tubercular pleurisy, an index of increased activity of the tubercular process, seemed only too probable. As the patient, however, regained a relative degree of health in a short time, the probability seemed that the old pulmonary disease was a chronic bronchitis and emphysema with a bronchiectatic cavity at the left apex, that the kidney trouble was acute, and that both kidney and pleural lesion were due to some infectious agent, the onset of the disease beginning abruptly with a chill and all passing off in a few weeks, leaving the patient, as far as her pleura and kidneys were concerned, as it found her.

I wish, in closing, to say a few words upon the prognosis of pleurisy, or perhaps I should say of the cases which present the physical signs of pleurisy and nothing more, as upon this rests the importance of the recognition of the seemingly slight cases that I have chosen for my text. In the London *Lancet* of 1885, vol. i., is to be found a series of lectures by Sir Andrew Clark on "Primary Dry Pleurisies," in which he calls attention to the frequency with which fibroid phthisis develops from what in its inception is apparently dry pleurisy, often very latent symptomatically. From the pleura the fibroid process, which is generally unilateral, extends into the pulmonary parenchyma until the lung is more or less extensively crippled. The desirability of detecting such a case at the onset is too obvious to be insisted upon. It is perhaps not probable that any of my cases belonged to that category, as all began, progressed, and departed like acute infectious diseases. The middle-aged, stout, and flabby patient, however, was the kind of a patient to get up degenerative changes of one kind or another, and at an age at which fibroid phthisis is apt to develop. I suppose that few physicians to-day question the etiological importance of the tubercle bacillus. It is as generally recognized that a predisposition on the part of the patient, consisting either in constitutional or local vulnerability is essential to the implantation of the disease. A pleura damaged perhaps by just such a latent process as those above cited and not properly treated, simply because a proper diagnosis has not been made, may prove just such a predisposing cause. A patient whom I recently examined, having previously been a strong man, began to cough and have pain in his left side last December. The pain was severe on coughing or sneezing, but did not prevent him from working. When first examined by me he had dulness, defective motion, and pleuritic crepitation over the left lower lobe. The apices and the right lung were at that time free. He was, however, coughing up considerable yellow mucopus and was very weak and cachectic. The physical signs were those of an old pleurisy, the appearance and history were those of phthisis. Examination of the sputum showed quite numerous bacilli. It seems quite probable that in this case a primary pleurisy had acted as a local predisposing cause which had rendered possible the implantation of tubercular disease. Masked by the pleurisy there undoubtedly existed tubercular foci not recognizable by physical exploration.

Another case that I would like to mention was that of a man who claimed to have been healthy two weeks previous to admission to the hospital, when he was seized with acute pains across the body in the diaphragmatic region. These were present on admission. A rough friction followed by considerable effusion occurred on the left side, later a rough friction without appreciable effusion and lasting for several weeks, occurred on the right. On the left side the effusion diminished until it was reduced to a dull area corresponding to the portion of the lower lobe posterior to the axillary line. Over this area respiratory signs were absent, the voice-sounds distant, vocal fremitus abolished, and the hypodermic needle drew only blood. The movements of the thorax were less than on the other side, the left chest was, however, only one-fourth of an inch smaller than the right. There was, therefore, a mass of solid exudate in all probability occupying this area.

This case was of great interest, because double pleurisies are generally of constitutional origin and frequently tubercular. If the patient's statement could be relied on the onset of the disease was acute. The improvement in his condition, which would have been rapid for a tuberculosis case, and the absence of bacilli from the sputum told strongly against the tubercular origin of the case, a view that I was first inclined to take of it. A practical point of great importance to the patient was that I kept him in the general medical ward pending the making of a definite diagnosis instead of sending him into the ward devoted to phthisis patients. Had I done so, in a month's time his sputum would have probably been teeming with bacilli, and I would have been congratulating myself on my diagnostic acumen on false grounds.

My main object in bringing this little group of cases to your attention is to refresh your memories in regard to the occurrence of inflammations of the pleura, which are nearly or quite symptomatically latent, and to suggest the importance of their recognition. Diagnosis is often, as in the three cases cited at the beginning of the paper, not difficult if only the possibility of their occurrence is kept in mind and an intelligent analysis is made of the physical signs noted on repeated examination and of the history of the cases. Such cases come under the observation of the general practitioner rather than of the specialist. Upon him devolves the grave responsibility of diagnosing and treating most diseases in their incipiency. Upon the breadth of his knowledge, the acuteness of his powers of observation, and the soundness of his judgment hangs the fate of the patient, rather than upon the skill of the specialist, who often is consulted only after disease has progressed beyond remedy. The task especially of stamping out that great scourge of our race, pulmonary tuberculosis and its kindred diseases, devolves upon the great body of the profession. The habit should be more generally cultivated by us all of observing the constitutional tendencies of patients, and even when the disease in question in a given case is trifling, we should systematically look beyond the present disorder and consider what light it sheds upon the patient's future prospects.

THE EXCLUSION OF LIGHT IS NOT BENEFICIAL IN THE AFTER-TREATMENT OF CATARACT OPERATIONS.

By JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND, AND SURGEON IN CHIEF OF THE PRESBYTERIAN EYE, EAR, AND THROAT CHARITY HOSPITAL OF BALTIMORE CITY.

CONSERVATISM in medicine often resembles a rut, more or less deep, in which thought or want of thought can be well hidden by those who are constantly traversing this special road. We get into certain ways of doing a thing, whether these be right or wrong, useful or useless. It often needs some convulsion, a little short of a dynamite explosion, to lift us out of this well worn groove. When we get accidentally on the upper surface we observe that there are other roads to the goal for which we are striving, some smoother and more direct than the one which we had so long used. We would never have discovered these, had not accident forced us out of the old well-trodden path. In this category I place the orthodox, called classic, after-treatment of cataract operations.

For many years but one stereotyped method has been followed by ophthalmic surgeons, when everything else was changing around them. Instruments and manipulations were all being modified for the better, but the old habitual, faulty bandaging of eyes remained.

This bandaging of eyes was a plan devised long ago by a leading surgeon, when ophthalmic surgeons of note were few. It was adopted by those who followed his teaching, and in time it became general. It was based upon the prevailing belief that absolute quiet in the dark was necessary for the healing of a corneal wound. The plan selected was as follows: After the clean wound was made by the sharpest of instrument, and the opaque lens was removed from the eye, both eyes were covered by soft compresses which were well secured in position by bandaging the head. The patient was then put to bed in a room from which all light was shut out. In this dark chamber he was kept absolutely quiet, all causes for excitement being carefully excluded. In this condition of seclusion he was constantly watched for eight days. The bandages were removed daily for eye-inspection by candle-light, and were then replaced. At the end of eight days the corneal wound was presumed to have healed, and the bandages were no longer continued. On account of the absolute darkness to which the eyes had been submitted for so long a time, they would exhibit extreme irritability when exposed to the least light. The windows of the chambers were therefore covered by heavy curtains, until such a time as the eyes had regained some little of their former strength. Under the protection of dark-smoked glasses and brow shades, light was day by day slowly admitted, until ordinary day-light could be borne. Good results came to the patient from the carefully performed operation, and under the confining treatment. It was these final good results which were so much to be desired. Hence one surgeon after another fell into this rutty method of treating such cases. The dark room, with bed confinement and absolute quiet, became the orthodox treatment of cataract patients. No one questioned the propriety of this course, so universally adopted.

I got into the rut which my teachers had so well trodden, and for twenty-five years I steadily followed this classic method of dressing and treating my cataract patients. In hundreds of cases, after cataract and iridectomy operations, I followed this restraining and confining method without questioning its value. In visiting such patients at noonday, a candle was a necessary and constant companion to see one's way in the dark sick-room. This routine is still kept up by many. It is one of the relics which ophthalmic surgery has not yet shaken off.

The large pledget of soft lint which was secured over both eyes adapts itself to the irregularities of the socket, and is supposed to exert an equable pressure over the whole front of the eyeball, keeping it quiet and promoting healing thereby. When after one week's confinement in the dark room the bandages are removed, the sensitive eyes stream with tears. This symptom is explained as the natural consequence of the operation. We expect to see this weeping of the eyes when the bandages are finally taken off after the eight days of confinement, and we are never disappointed. All eyes weep in the dark after the removal of the confining cataract dressings.

Four years ago I began to doubt the propriety of this universally adopted method of treating cataract patients. I first questioned the confiding faith in the supporting bandage. The eye, after cataract extraction, presented itself to me as a hollow elastic ball, with an incision made into its upper surface of one-third the circumference of the cornea. As I inspected it, when the extraction operation had been completed, the lips of the wound adjusted themselves so perfectly to the opposing surfaces as to exclude detection. Here was a perfect adaptation which the closing of the lids did not disturb. If I pressed upon the centre of the cornea the wound showed a disposition to gape, which tendency disappeared the moment pressure was relieved. The question which suggested itself to my mind was this, viz., Did not the compress, secured over the eye, make just such pressure upon the prominent cornea as I had made with my instrument, and was not a tendency to disturbance created by its presence? As the patient lay upon the operating-table with eyes closed, I knew that the adjustment was perfect, and the eye in the very best condition for rapid healing. If I could keep it in that condition for only a few days I felt that the wound must cicatrize, and that the very best results would be secured. How to keep it so was the question. It seemed to be rationally answered by this suggestion: Keep the lids together by the careful application of a piece of light, non-irritating, diaphanous adhesive plaster, rather than by thick compresses and bandages.

I adopted this method of treatment. A piece of salicylated soft silk, isinglass plaster, one and a half inch long and one inch wide, was placed upon the closed eyelids. It extended from beneath the brow well down upon the cheek. It was not as wide as the lids, and therefore left the angular margins exposed for the ready escape of secretions, and also for the instillation of eye-drops, without the displacement or removal of the retaining plaster. When dampened by a little water and its surface pressed by a spatula, in its wet, limp condition it adapted itself to every irregularity of the lid surface. In drying, it kept the lids together as if they had been an unbroken septum, and that without making irregular pressure upon the cut eyeball. The plaster being diaphanous, every lash could be seen as it lay stretched out on the cheek. The eyelids could be inspected through the plaster dressing as when the compresses are removed for the daily examination under the old treatment. This seemed to be, theoretically at least, a perfect eye dressing.

My first experiments were watched from day to day with anxious care. I always found some secretions escaping, seldom enough to detach the plaster, and never enough to disturb its transparency or to interfere with the inspection. In the old treatment I daily examined the eye-cloths and compresses. If comparatively clean, I accepted their condition as an index of the absence of inflammation, and this without looking into the eye itself. The appearance of the adhesive strip, without its removal, I found an equally good index of the condition of the eye. It does away with all eye-disturbances from the daily renewal of dressings. After the eight days of watching, when the plasters were removed, I found thoroughly healed corneal wounds, in every way as perfect as when compresses had been used. The comfort to the patient under the new dressing had been very much enhanced, no head-bands to annoy, or to slip, or to be renewed from time to time. This was an immense improvement over the old method. The adhesive plaster so soon proved itself a simple and efficient dressing that it usurped the

place which compresses and bandages had heretofore held in my estimation.

Once having abandoned the so called classic method of dressing an eye after cataract and iridectomy operations, the accompaniments of this treatment, upon which so much stress is laid, were one by one modified. The first very important item to be set aside was the dark window curtains and the closed shutters. If the closed eye from which the cataract had just been removed was not inconvenienced by the strong light of the operating room, I saw no reason why it should not continue to submit comfortably to this exposure. Now, in my practice, a window shade to shut out strong light is the extent of screening found needful.

The next move was to leave uncovered the eye not operated upon, in which there was still some useful sight. With this eye open, and in a moderately lighted room, patients were never for a moment in the dark. They could see to help themselves in many ways, and they appreciated immensely this modification of the old treatment.

The next attack was made upon bodily restraints: the confinement in bed, on their backs, with instructions to keep quiet, and for one or two days to chew nothing, so that the movement of the jaws would not disturb the healing of the cornea. Experience had proven to me that the movements of the exposed eye did not disturb the healing of the cut one, and therefore the movements of the legs, hands, and jaws were less likely to do so. Bed treatment was therefore abandoned. As my daily experience was forcing upon me the recognition of the fact that absolute quiet was not an essential in the successful treatment of cataract extractions, my patients were allowed to move about in moderation. As time wore on, and my percentage of successes steadily increased with the liberties which my patients enjoyed, I became the more confirmed in the value of my modifications in the treatment of such cases.

In the meantime, the removal of cataracts without iridectomy was introduced. I, with others, accepted this improvement, and for the past two years have left the iris intact, with pupil undisturbed. A *sine qua non* for the success of this new operation, we were told, was that patients must be kept absolutely quiet on their backs in bed; that the least jolting would open the corneal wound and allow a piece of the iris to protrude, causing the serious complication of an iritic hernia with ugly results. So confident had I become in the thorough support which the lids, closed by adhesive plaster, gave to the eyeball and the cut cornea, that I made no change in the dressings, nor in the after-treatment for the new operation. My results were equally satisfactory with those who used every bodily restraint. In my early operations without iridectomy, I had every now and then a hernia of the iris; but so had those who adhered to the old method of dressing with bed treatment. I could not attribute this accident to the after-treatment, because it occurred where either method was carefully used. I was more disposed to explain it by some fault in the manual of operative procedure, which I hoped that time and a greater familiarity would overcome. This has proven to be correct. A prolapse of iris now very seldom occurs in my practice.

In cases in which there had been loss of vitreous during the extraction, my superstitious reverence for the imaginary protection of a compress and bandage made me doubt at first the propriety of trusting the eye to the adhesive strap. This feeling I have quite outgrown. Even in these cases I now rely with confidence upon the equable support of the adhesive strap as the sole and universal eye-dressing. If it is carefully applied it will, as a rule, remain on securely for many days, regardless of the escape of secretions. Should I find it loosening on the second or third day, I remove the old piece and adjust a fresh one. If it does not become displaced before the fourth or fifth day, I do not find it necessary to replace it, because by this time the corneal wound is quite healed and needs no longer protection.

Now and then a case presents itself in which the very stiff out-curved eyelashes will not lie smoothly on the cheek under the adhesive dressing. They tend to lift the plaster in a groove along the free border of the lid. They prevent the perfect adjustment of the plaster. It will stick well upon the smooth surface of the eyelid and also on the cheek, but remains irregularly adherent to the lashes. At first this condition annoyed me much, and I would make repeated attempts to get a fresh piece of plaster to lie more smoothly. Now I no longer regard it. Experience has taught me that, should a little lid separation exist after the dressing is applied, no harm comes from it. I have had patients blind in both eyes with one operated upon, remark, an hour after the extraction, that they could peep out of the newly operated eye and see objects dimly. No injury would come from this apparent liberty. The wounded part of the eyeball is always thoroughly covered, supported, and protected by lid-pressure, and that is all that is required for promoting quick healing.

The most striking results of this unrestraining treatment of cataract patients in light-rooms is the comparative freedom from weeping which the eye exhibits when the adhesive strap is removed and the eye is permanently exposed, even as early as the fifth day. This is to me very conspicuous when I examine the hospital work of other specialists who still adhere to the dark-room confinement. Red, watery, painful eyes they expect to see, and are never disappointed. In my practice such red and watery eyes form a decided exception to the rule of comparatively dry, non-congested eyes. This very satisfactory condition I attribute solely to my change in the after treatment. The red, watery eyes I formerly had, as specialists still have, when I kept patients in the dark for days as they do.

My present method of treating cataract extractions is as follows: I try to make the manual of operation as smooth in every particular as I possibly can, using for asepsis instruments which I had previously immersed in boiling water. I use no antiseptic liquid on eye or face of patient, or on instruments. If the surface of the eye is in a healthy condition, I do not believe that pyogenic germs have collected on the conjunctiva, awaiting their opportunity to rush into the corneal wound as soon as formed; therefore I no longer go through the useless form of washing out the conjunctival sac. I see many surgeons put a few drops of a necessarily weak germicide solution on the eye, and immediately afterward proceed to make the corneal section. If the pyogenic germs were there no harm could come to them from this very transient water-bath. Bacteriologists are very much amused at the superstitious reverence of the modern surgeon who goes through this veriest form, and imagines that he has performed a most important duty. I have broken away from this useless habit of many, of trying to fight malignant bacteria which are not present by the momentary use of weak germicides which can do them no injury. I adhere rigidly to cleanliness for protection. Under the anæsthetic influence of a four per cent. solution of cocaine, I make a large corneal opening in senile cataracts, following the sclero-corneal circle for nearly one-third of its circumference. I find that this kind of opening, just where the clear cornea ends, facilitates the easy exit of the lens. Cutting across the clear cornea, as is often done in the iridectomy extraction, leaves a corneal shelf which obstructs the escape of the lens. After the corneal section I introduce the cystotome, and with it I thoroughly tear up the capsule over the pupillary area.

At one time I practised opening the capsule with the point of the cataract-knife as it traversed the aqueous chamber. This was a brilliant manœuvre with which I was much pleased. I found that in some cases it increased the difficulties of making a smooth operation. The lens would jump forward when the incision into the capsule released it. This movement would sometimes push the iris

over the edge of the knife. It was not always easy to dislodge it, or to avoid injury to the iris in completing the corneal section. In some cases I was forced to make an iridectomy when I had not so intended. I have, therefore, given up this step for the safer method of releasing the lens after the corneal incision had been perfected.

When the corneal wound is large enough, and is well placed at the uppermost circle of the clear cornea, the pressure of a shell-spoon upon the lower part of the eyeball tilts the upper edge of the lens forward and starts its delivery. The iris at first caps it, but by continued pressure the pupil expands, the iritic curtain gets out of the way, and the lens escapes through the corneal opening. There is usually some soft lens-matter left which can all be coaxed out by the careful pressure of the spoon. The pupil then regains its black color. If the speculum does not compress the eyeball, the iris will most frequently, without external aid, resume its proper place within the anterior chamber. Should it show a disposition to lag at the corneal wound, it is replaced in the eye-chamber by a few strokes of a spatula. When one becomes familiar by an every-day experience, he no longer wonders at the liberties which, under dexterous manipulation, can be safely taken with even this delicate, sensitive membrane. With the spatula the iris is not only pushed back under the cornea, but by sundry gentle strokes it can be smoothed out until the pupil assumes its normal size and appearance. The eye then looks as perfect as if no operation had been yet made, and fingers can be readily counted by the patient. This little trial assures them of the success of the operation, and gives the blind a foretaste of the good things to come.

The speculum is now removed and a few drops of a solution of eserine, three grains to an ounce of water, are put on the cornea. The object of these drops is to procure a decided and protracted contraction of the pupil. Both eyes are temporarily closed, and the eye from which the cataract had been removed is ready for its single and simple dressing. The adhesive strip is placed in position over the eyelids. If the secretions from the eye are not sufficient to make it stick it is moistened. When stroked by the shell-spoon it lies smoothly over the lid and cheek. Any excess of moisture is removed by the gentle pressure of a fold of a soft towel. In a few minutes the plaster dries. The cut eye is now shut in from all harm by having the lids permanently stretched out over it as a supporting mould. The patient can open the other eye, and without fear of injury can walk unaided from the operating-room to his own chamber.

Usually the excitement of the operation is followed by some lassitude, and patients prefer to lie on the bed. If they be of the more stolid kind, and prefer sitting or reclining on a couch, no objection is made to it. Operations are always performed by me after 2 P.M., when my morning's office work is finished. When supper-time comes, by the aid of the eye not covered, patients can partake of the evening meal without being fed. They are also allowed to make their own toilet at bed-time. As an aid in keeping the pupil contracted, and the iris away from the corneal wound, a few drops of the eserine solution are put at the inner canthus of the closed eye at bed-time. These find their way into the eye without displacing the adhesive strip. As they often cause brow ache and some pain in the eye, which might interfere with quiet sleep, a bromide or chloral mixture is given as a sleeping dose. The following morning a few of the eserine drops are again instilled, and with this drop ends all applications to the closed eye. If they desire it, patients get up at their usual rising hour, making their own toilet. This they do the day after the operation. The consecutive ones are spent sitting or reclining, seeing friends, if they desire it, and partaking of regular solid meals. The closed eye is inspected daily to note whether there has been much discharge of eye-secretions. Also to discover if there be any tendency to displacement of the adhesive strip. Often, after the second day, the plaster at its centre, along the lid border, seems to have been liberated from the lashes, forming a loose groove the whole length of the lid-split. Experience has taught me that this does not interfere with the most perfect final results.

Day by day I watch the appearance of the lids through the diaphanous dressing. The good light in the room permits this thorough examination. By the fifth day, should there have been no evidence of suppuration, I know that the corneal wound has healed, and I remove the adhesive dressing. Sometimes I wet it before removal, at other times I detach it from the eye dry, and then bathe the eye with warm water to get rid of all sticky matter, remnants of the adhesive substance from the plaster, and desiccated eye-secretions, the accumulation of five days' collection.

As a rule, when the eye is liberated in the light-room it is not much injected, nor does it run much water. From this time forth it is left uncovered and unprotected. The only treatment for the recently operated upon eye is the instillation of a few drops of a four-grain solution of the sulphate of atropia, for the purpose of breaking up any recent adhesions which may have formed between the iris and the lens capsule.

After from eight to ten days, when the eye no longer feels weak in the subdued light of the chamber, the window-shade is partly raised for the admission of more light. At the end of two weeks, patients can usually stand the full light of the open window, and can go about the house, provided they keep out of the strong sun-light. When dismissed from the hospital, they go away without having worn smoked glasses. They are warned to keep out of the sun, and to follow this simple rule as to exposure, *any light that is not uncomfortable to the eyes will not be injurious.* Those after cataract operation who find sun-light not painful, will not be injured by going into it. I find that a great many can go into the street with uncovered eyes, and without discomfort, two weeks after a cataract extraction, provided the whole treatment has been conducted in light-rooms with the one eye unprotected continuously exposed to the light.

In other words, my four years' experience with the treatment of cataract patients after operation, in many hundred cases shows very positively, that the weakness of eyes operated upon is not so much the result of the operation, but depends in a large measure upon the after-treatment to which they are subjected. Good, healthy eyes, kept in darkness for one week, cannot stand the light when exposed to it. Eyes that have never been in the dark exhibit no such irritation.

I am glad to know that this line of treatment, so revolutionary in its nature, which originated at the Presbyterian Eye, Ear, and Throat Charity Hospital, of Baltimore City, four years ago, has made itself felt throughout this country, and is being adopted by some of the specialists of Europe. I hope that the day is not far off when the harsh and useless treatment of bed confinement, in the dark, with the many bodily restraints which have been imposed upon cataract patients, will only be read about as evidences of what superstitions formerly pervaded the medical mind; also as illustrations of the wonderful docility of patients, who quietly submitted to a treatment against which they had such good reasons for rebelling.

A Dangerous Mineral Water.—William T. Jeffries and S. S. Jordan have filed a bill in equity in the United States Circuit Court against the Geneva Magnetic Water Company, of Washington, D. C., W. L. Cresson, of Norristown, and Julius Hugle and J. C. Ergood, of Washington, to recover moneys in an odd business transaction. They purchased rights for the sale of the magnetic water in certain counties, understanding that it contained no organic matter, and, as they claim, have since discovered that it is injurious.

An epidemic resembling yellow fever is raging at Belize, Honduras.

THE SUBSEQUENT HISTORY OF A CASE OF NEPHRECTOMY PERFORMED IN 1885.

By FRANCIS J. SHEPHERD, M.D.,

SURGEON TO THE MONTREAL GENERAL HOSPITAL.

In the RECORD for December 12, 1885, I reported a successful case of "Nephrectomy for Calculous Pyelitis," and wish now to place on record the after-history. The patient, a married woman aged twenty-four, was operated on by me in September, 1885, and the left kidney removed. At the time of the operation she was in a state of extreme emaciation, and hence the right kidney could be palpated with ease. It was apparently perfectly normal. The woman recovered quickly from the operation, and left the hospital at the end of a month with a small sinus at site of operation; this sinus healed rapidly some months later, after the discharge of the ligature which surrounded the vessels at the hilus. I saw her occasionally during the next two years, and she was evidently in robust health, her urine, which was frequently examined, was normal in quantity and appearance—within fourteen months of the operation she gave birth to a healthy child. I did not see her again until the fall of 1888, when she came to me complaining of "thick urine," and pain in the right lumbar region. She was admitted into the hospital, and her urine was found to contain a considerable quantity of pus. As she was at this time pregnant, although I advised operation, I did not press it upon her; she, however, declined any further operative interference. After a stay in hospital of a couple of weeks, she was discharged much improved. The pus had entirely disappeared from the urine and she had very little pain. No tumor could be detected at any time in the region of the right kidney. She again presented herself in the fall of 1889, and was admitted into hospital; her urine was loaded with pus, and she had latterly lost flesh. No kidney tumor could be made out. I strongly advised an exploratory operation, but she said as she had only one kidney she meant to keep it, and no persuasion would induce her to submit to operation of any kind. She left hospital in a week, somewhat improved, and I heard nothing of her until the end of the last week of April, 1890. Her husband came to me and said his wife, who had lately been confined (of her third child since the operation), was very poorly, and he thought she would not live long. I had her immediately brought to hospital and found her in so serious a condition that very careful examination was not attempted. For some time previously she had been passing daily only from eight to ten ounces of urine, loaded with pus. While in hospital, she passed during the last two days only four ounces of urine, her pulse was shabby, temperature subnormal, expression dull and stupid, was continually vomiting, and emitted a distinctly urinous odor. She died on May 4, 1890.

The following is taken from the report of autopsy held May 5th by Dr. W. G. Johnston, pathologist to the hospital:

"Body of a well-nourished, average-sized woman; subcutaneous fat abundant. . . A depressed cicatrix four inches long runs obliquely above the ilium in the left flank. . . In abdomen left kidney absent. Upper end of left ureter cannot be found. No adhesions or thickening in the left lumbar region; position of descending colon normal. Right kidney greatly enlarged, reaching from the crest of the ilium to the level of the seventh rib behind. Connective tissue and fat about the hilus much increased, and the aortic glands on right side at this level form a mass about the size of an egg. Kidney removed with pelvic organs. It forms a large fluctuating sac and contains over twelve ounces of thick muco-purulent urine. After opening, it weighed three hundred and fifty grammes. The upper half of the organ is transformed into a series of communicating sacs with granulating walls, the renal substance being reduced to a narrow zone one-eighth of an inch thick immediately beneath the capsule. The outlet for this half of the kidney is a narrow passage, admitting a No. 10 catheter running through the mass of fat and connective tissue at the hilus, to enter the pelvis proper of the kidney. This passage is blocked by a hard yellow-brown calculus, weighing ten grammes, which has a sharp conical point projecting down into the pelvis, and several branches with expanded ends extending into the dilated calyces. These ends are tipped with a rough white crystalline deposit. In the recesses of the saeculi are several small flat, rough calculi. The lower half of the kidney is far less altered. The pelvis and calyces are somewhat dilated and their mucosa thickened and rough, but the renal tissue is still an inch or more in thickness. There are no signs of calculi in this region. In the right ureter the mucosa is thickened, rough, and slaty-gray in color. The lumen is narrowed slightly and is filled with muco pus. The entrance to the bladder is normal. The left ureter is shrunken, with a dense fibrous cord which can be traced as far up as the brim of the pelvis; no probe can be passed into it. Remaining organs healthy."

No doubt, had I operated on this patient when pus first began to appear in the urine, she might have lived for many years.

Progress of Medical Science.

The Innervation of the Stomach.—Two Russian observers have recently undertaken a series of elaborate experiments tending to elucidate the question of gastric innervation. A summary of their conclusions is given by the *London Medical Recorder*, as follows: 1. Normal movements of the stomach attain their maximum intensity during the gastric digestion, that is, when the organ is filled up with food masses. When the organ is empty, its movements not unfrequently cease altogether. 2. Given an active period, there are usually observed more or less strong rhythmic contractions of the pyloric portion of the organ, which occur at a fairly regular rate. The cardiac portion of the stomach may frequently remain at rest. It commences to perform periodic contractions only when the active period reaches its height, the contractions being more slow in comparison with the pyloric ones. They are not strictly synchronous with the latter; not unfrequently the movements of the cardia coincide with relaxation of the pylorus, and relaxation of the cardia with pyloric contractions. 3. At the height of the gastric action, there are observed, in addition, fairly strong general contractions of the gastric walls, running from the cardia toward the pylorus. They may sometimes occur even in such cases where the pyloric contractions are weak or absent altogether. 4. The pyloric movements are mainly dependent upon a peripheral or local nerve apparatus, since they may still occur even after both of the vagi and the cervical portion of the spinal cord have been divided. 5. They are, however, kept up and even excited by the agency of the vagi, since division of the latter alone may prove sufficient to cause a complete cessation, or at least a more or less considerable weakening, of the rhythmic movements. 6. On the other hand, destruction of certain portions of the central nervous system (*e.g.*, corpus quadrigeminum) similarly gives rise to a more or less prolonged stoppage of the pyloric contractions, which, however, after some while, regain their former intensity. 7. Stimulation of the vagi is invariably followed by very strong and accelerated rhythmic contractions of the pyloric region. Irritation of the right pneumogastric nerve always produces more pronounced effects than that of the left one. 8. Stimulation of the vagi never brings about a continuous constriction of the region; hence the supposition is justified that the nerves act on the region through stimulating a local peripheral nerve-apparatus. 9. As regards the cardia, strong electric and even mechanical stimulations of the vagi invariably produce a general contraction and constriction of the region, while a slight electric irritation gives rise

to a more or less marked dilatation of the part, the pylorus showing no changes at the time. (In other words, the authors confirm Openkhovsky's observations, according to which the vagi contain cardio-dilating fibres.) 10. When the stomach is empty, simulation of the vagi manifests a by far weaker influence on the organ than during the period of digestion. 11. An increased frequency of the pyloric rhythmic contractions is also observed on electric stimulation of the medulla oblongata. 12. Stimulation of the splanchnic nerves invariably completely arrests the pyloric movements (that is, the nerves contain special pyloro-inhibitory fibres, as Openkhovsky has shown), and at the same time induces a prolonged, though weak, single contraction of the organ, spreading from the cardia to the pylorus. 13. The same effects are also obtained from stimulating the spinal cord (its upper part), medulla oblongata, cerebral pedunculi, and anterior segment of the optic thalamus. The latter contains special centres inhibiting the pyloric movements. 14. Stimulation of the sigmoid gyrus (especially of its postero-external, but partly also of the anterior, portion) increases the pyloric contractions, the increase being often accompanied by a general constriction of the region, and followed by some decrease, or even temporary complete arrest of the movements. Now and then the same effects may be also obtained from stimulating the second gyrus, in the neighborhood of the sigmoid, and the third or fourth ones, between the upper end of the Sylvian fissure and postero-external division of the sigmoid gyrus. 15. Stimulation of the anterior part of the sigmoid gyrus, and sometimes of the outer end of the cruciate one, as well as of the posterior division of the sigmoid and adjacent part of the second primary gyrus, gives rise to a more or less prolonged retardation, or a complete inhibition of the pyloric contractions, accompanied by a general constriction of the region, and followed by increased movements. 16. Stimulation of the antero-external division of the sigmoid gyrus may occasionally give rise to contractions of the cardia without producing any changes about the pylorus; while irritation of the posterior end of the same gyrus may sometimes call forth contractions of the cardia, accompanied by increased pyloric movements. 17. As to a reflex influence of peripheral stimulation, it has usually an inhibitory character. With regard to the energy of the action, the peritoneal coat of the intestines and the peritoneum in general must be placed foremost. Even a slightest stimulation of the parts, such as a gentle stroking with a finger, very rapidly brings about a total and more or less prolonged arrest of all pyloric movements. Similarly, any cutaneous stimulation (pathic or thermic) gives rise to a temporary decrease or stoppage of all gastric contractions. The same holds true in regard to rhythmic contractions of the small bowel. 18. Stimulation of the central end of a divided vagus produces a temporary arrest of the pyloric rhythmic movements, accompanied by a general contraction of the gastric fundus, and a quite distinct dilatation of the cardia.

A New Theory on Labyrinthine Vertigo.—The influence of labyrinthine impressions on the maintenance of equilibrium of the body is now generally believed to have been demonstrated by the experiments of Flourens on the semicircular canals of pigeons, and to have been confirmed by the pathological researches of Menière. Indeed, all text-books contain the doctrine that destruction of these canals produces definite and special disturbances of equilibration, which render any proper co-ordination of locomotion impossible. Many years ago, however, Schiff protested against this theory, on the ground that section of the trunk of the auditory nerve did not cause any disturbance of equilibrium; while, more recently, Böttcher drew attention to the circumstance that in pigeons, on which these experiments have generally been made, the canals cannot, for anatomical reasons, be destroyed without injuring at the same time the cerebellum, thus giving a fruitful source of errors. The most serious objections to this theory have, however, now been raised by Professor Steiner, of Cologne, who has experimented on sharks caught in the Bay of Naples, in which class of fish the semicircular canals are particularly developed, and which are, therefore, most suitable for such experiments. The skeleton of sharks being cartilaginous, laying bare the semicircular canals is very easy; they are superficially situated beneath the skin, and separated from the brain by a considerable mass of cartilage, so that injury to the brain can be easily avoided. Steiner has found that when the membranous canals of sharks are laid bare and excised, and the wound is then closed and the fish put back into the water, not the slightest disturbance of locomotion ever follows. On the contrary, if after laying bare the labyrinth, the trunk of the auditory nerve, or the ossicles surrounding the same, are pulled and stretched, then there is invariably a disturbance produced in the form of rotatory or circular compulsory movements. If the latter operation be performed unilaterally, the direction which such movements take may in each case be predicted. Such traction of the nerve-trunk need only be slight in order to produce motor disturbance. The same result follows if no section of the canals be made, but one of them is pulled and stretched so that the ossicles change their position. These experiments show that in sharks the semicircular canals have, by themselves, nothing to do with equilibration, and that when motor disturbances follow, they are owing to traction and irritation of the origin of the auditory nerve in the medulla oblongata, and are the same as are produced by other similar irritation of that portion of the medulla. Steiner has shown that the same results, as in sharks, are obtained in frogs and lizards. In the higher vertebrates the anatomical relations of the parts concerned are so complicated that it has hitherto been found impossible to avoid sources of error in experimentation. Ewald's recent experiments on pigeons likewise seem to lead to similar conclusions. In one experiment he removed the six ampullæ from a pigeon, which survived the operation, and being very tame, followed him afterward, in a straight line, through several rooms. The same animal, however, when left to itself, was apt to walk in a circle, sometimes to the right, and sometimes to the left side. Why should the animal walk straight when following its master and in a circle when left to itself? Steiner explains this by assuming that compulsory movements are produced by the loss of cutaneous and muscular impressions consequent upon the operation, and that this loss may be neutralized in the higher animals by the influence of the eye and the intellect upon movements. The pigeon, therefore, overcomes the tendency to compulsory movements by fixing its attention upon the movements of its master. The vertigo of Menière's disease would, therefore, appear to have its source rather in lesions which affect the brain or its membranes, or cause alterations of pressure. That the semicircular canals have nothing to do with it is also shown by a case recorded by Politzer, in which there was congenital absence of all semicircular canals, yet no disturbances of equilibration had taken place during life; and another one of Lucae, in which the canals were found filled with blood-clots, and where there had been before death no corresponding symptoms showing that this condition had interfered with equilibration.—*The British Medical Journal.*

Frau Rosa Kerschbaumer, the wife of a physician, formerly assistant to Arlt, in Vienna, has obtained permission to practise medicine in Austria. This is said to be the first instance in which such a privilege has been granted to any woman in that benighted country. The lady was graduated in medicine in the university of Berne, and has for some time practised in company with her husband in Salzburg, her work, however, being done secretly, her husband being responsible for all that she did as a physician.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, August 2, 1890.

THE REMOTE RESULTS OF REMOVAL OF THE TUBES AND OVARIES.

GYNECOLOGISTS are showing a praiseworthy endeavor to find out what are the remote results of removing ovaries and tubes, and what is the final condition of the patient who has been operated upon. It was at first thought a sufficient justification of laparotomy if some diseased structure was found and removed. This was taking a purely surgical view of the case and not that of a patient, or even of a disinterested observer. If the patient is no better, or even worse, after a diseased structure is removed, she may reasonably assert that the operation was practically and personally a failure.

We have published some of the discussion which took place upon this subject before the Section on Obstetrics of the Academy of Medicine last April. A full report of one of the papers then read—that by Dr. Howard A. Kelly—has just been sent us (*Johns Hopkins Hospital Bulletin*). It gives a very fair idea of the position which the gynecologist still holds upon this matter, and of the intellectual limitations which the practice of oöphorectomy seems invariably to impose.

Dr. Kelly bases his remarks upon 96 cases of tubal and ovarian disease for which laparotomy was done between the years 1886 and 1888. Among these are, first, 25 cases of tubo-ovarian abscess. Some of the unpleasant sequelæ are cited as follows: Two cases had uterine hemorrhages; 3 cases had fecal fistula, and one of these a urinary fistula also; 2 cases had encysted masses left near the womb; 2 cases had hernia; 2 cases continued to have the same headaches as before.

Aside from these, Dr. Kelly says that the patients were all cured—that is to say, 13 out of the 25; and he adds that he does not know of a single case "not improved."

Out of 33 cases of salpingitis and ovaritis, whose condition he knows, 13 were cured and 17 improved. Of the remaining 3, 1 died from causes unknown, 1 still has distressing dysuria, 1 is not improved.

Out of 25 cases of lesser disease of the ovaries and tubes 8 were cured, 7 very much improved, 13 improved, 5 slightly improved, 2 not much better. The arithmetical process by which 8, 7, 13, 5, and 2, are made to amount to 25 is unique, but we will lay the blame on the printer. It seems, however, that out of the total 35 only 8 are cured. Among all the three classes of cases, therefore, it seems that the cures were 32, or about one-third. Of the remainder there was a large proportion suffering from various delicately differentiated degrees of improvement.

The writer admits no positively bad results. His standard of what is cure and what is improvement is largely a surgical one, based upon a consideration of the local condition. There is little note made of the general condition of health, and capacity for work and enjoyment; the marked and peculiar influence which a removal of the ovaries has upon neurotic women; its alleged tendency in some cases to cause insanity is not referred to, and probably was not observed by the writer.

On the whole, however, Dr. Kelly takes a reasonable view of the indications and effects of the operation, and he candidly admits that in estimating its results one should consider not only the possible mortality, but also the immediate accidents, such as hernia, fistula, hemorrhage, etc. He urges that, like an amputation, its results must be often justified in that it saves from worse suffering and possibly from death.

From a practical stand point, he adds, in conclusion, there are two classes of cases in which the operation is called for. They are the necessary and the elective.

"Salpingo-oöphorectomy performed for fibroid tumors choking the pelvis and pressing on rectum and ureters, and for pyosalpinx, is an operation necessary to save life. Salpingo-oöphorectomy performed for chronically inflamed ovaries and tubes, or for small ovarian cysts or blood cysts of the ovaries, is a purely elective operation.

"The results of salpingo-oöphorectomy should be divided into two classes, connected by the bridge of time—first, those results which at once follow in the train of the operation, and secondly, those symptoms which persist or crop out after months or years—the immediate and the remote results.

"In estimating the results we must never lose sight of the fact that the suffering which immediately follows an operation, even though the patient be completely cured by it, is to be weighed against the operation along with its mortality, the accidents of fecal fistulæ, injured ureters, fistulous drainage tracks, hernia, ileus, and all pain from adhesions and other sequelæ. Among the remoter results are uterine hemorrhages, hernia, late discharge of the ligatures, and I might include here persistence of pain which it had been expected the operation would relieve."

PRECAUTIONS IN PRESCRIBING CALOMEL.

IN times not yet long past it was the rule to caution all to whom a dose of calomel had been given to abstain for a while from salty and acid food; the reason for this precaution being, of course, the belief that calomel in the presence of strong acids or of chloride of sodium would be changed to corrosive sublimate. We doubt whether this rule is followed so strictly at the present time as it was a quarter of a century ago—in fact we are positive that it is not—and yet instances of poisoning from small doses of the mild chloride of mercury, in which the symptoms would render it probable that the conversion into the bichloride had taken place, are certainly exceedingly rare. It would seem, therefore, as if the precautions taken by a former generation were needless, and clinical experience is strengthened by theory when we consider that if this change ever took place in the body it should

always, since the contents of the stomach are usually acid, and ought to convert at least a portion of the ingested calomel into bichloride of mercury. A correspondent of the *Revue Générale de Clinique et de Thérapeutique* makes a somewhat similar suggestion in a recent issue of that journal, and asks if this is not, after all, a therapeutic superstition. In his reply the accomplished editor of the journal, Dr. Henri Huchard, recalls the chemical properties of calomel. It is, first, insoluble in water. Alkalies transform it into metallic mercury and the bichloride. Concentrated hydrochloric acid, with the aid of heat, transforms it into the bichloride; so also in a measure do alkaline chlorides and alkaline iodides at ordinary temperatures. Finally, hydrocyanic acid in the presence of calomel converts it into metallic mercury and the bichloride. Of course it does not follow that the same reactions will occur in the stomach, and it is not always safe to argue from the laboratory to the human organism. It is true that the stomach normally contains acids which, in a test-tube, would convert the chloride into the bichloride, and that many persons partake freely of salty and acid foods after a dose of calomel, and suffer no evil consequences therefrom. Nevertheless, there is no harm in being prudent, especially when it is so easy, as in this case; and we think, therefore, that Dr. Huchard's conclusions are well worthy of being observed. These are as follows:

1. All the alkaline chlorides are incompatible with calomel, and we should therefore forbid all salt food after a dose of calomel has been given.

2. In certain diseases calomel is prescribed in fractional doses at the same time that the patient is taking iodide of potassium; now, as this salt causes the conversion of the chloride into the bichloride, it is the wiser course not to have the two drugs together in the stomach.

3. Calomel should never be prescribed in the same mixture with preparations containing hydrocyanic acid, such as cherry-laurel water and the like.

4. Some forbid all acid drinks after a dose of calomel has been taken; but as acids convert this salt into the bichloride only when they are in concentrated hot solutions, this precaution seems hardly worth observing.

THE ANNUAL REPORT OF THE NEW YORK CITY BOARD OF HEALTH.

For the first time in many years the New York City Board of Health has published an annual report. The reappearance of these volumes is the more satisfactory for the reason that the previous publications of the Board were most valuable statistical and scientifical documents. The present report for the year 1889 is short and contains little but statistical tables; nevertheless there is much in it of interest.

We learn that the number of inspections during 1889, made by the Sanitary and Police Inspectors, was 363,875. There were 44,511 milk inspections made, and 6,284 quarts of adulterated milk destroyed. Nearly a million and a half pounds of fruit and food were condemned and seized—a most striking comment on the necessity of such work, and of the moral status of fruit and food dealers.

At the Willard Parker Hospital for Contagious Diseases 705 persons were treated during the year.

The death-rate for 1889 was 25.13 per 1,000, not including still-births.

The decrease in deaths in 1889 over the annual average of the past ten years was 2,247.

There were reported, 122 deaths from surgical operations, 33 being from laparotomy.

The statistics of suicides are given fully, and carefully analyzed.

We trust that the Board may in future be able to add scientific papers to its statistical work.

POLYORROMENITIS, OR "CONCATO'S DISEASE."

We had feared that the flowers which bloom in the spring would have come and gone, dissipating their fragrance and disarticulating their petals beneath the arid sun of July without the announcement of a new disease. Our fears were groundless, however, thanks to the rich pathological resources of Italy and the keen observations of Dr. Concato, of Genoa. In the *Rivista clinica e therapeutica*, of February, 1890, this author describes a series of cases, presenting, as he thinks, new and peculiar symptoms. The patients suffer from a progressive and malignant inflammation of various serous membranes, the disease finally assuming the aspect of a severe type of pneumonia. In one case, for example, there was a peritonitis, double pleuritis, and beginning pericarditis. Death occurred on the thirteenth day. The autopsy showed fresh adhesions between the pleural surfaces, with fibrinous exudates in the form of pseudo-membranes above, and of a solid precipated mass at the base. In the other cases, of which there were five, there was also found fibrinous exudates in the pleural cavity, with evidences, less marked, of peritonitis and pericarditis. The peculiarity of the cases was the disproportion between the severity of the symptoms and the post mortem findings which were mainly those of a dry pleurisy. Aside from absence of sputum the cases resembled, clinically, those of pneumonia.

A bacteriological study of the cases by Dr. Bozzolo has given as yet negative results.

In justice to Dr. Concato it should be said that he did not propose the name of "Concato's Disease," but suggests the more scientific one of "polyorromenitis," which is interpreted as meaning a "phthisis of "serous membranes." Dr. Galvani Ercoles, however, patriotically prefers to call this Italian trouble "Concato's Disease."

There will always be enough doctors to supply all new diseases with distinctive proper names; but we sometimes fear that this richness in onymic material is being drawn upon too freely. It takes a little practice to say "polyorromenitis" without stumbling, but with proper self-restraint and considerable patience it can be done; and if the esteemed Signor Concato has really found a new disease, we should recommend to systematic writers and teachers practice with the Greek derivative rather than a timorous yielding to the eulaliac ease of pronouncing the perhaps immortal name of Concato.

CHLOROFORM ANÆSTHESIA.

The Hyderabad Chloroform Commission has just made its second report, completing the account of its work. The Glasgow Chloroform Committee has published a

critical report taking issue with the results of the Hyderabad Commission. Surgeon-Major Lawrie has written an article summarizing the work of the Hyderabad Commission, and replying to the criticisms of the Glasgow Committee. It will thus be seen that the question of chloroform anæsthesia remains yet unsettled. As it is to be discussed at the coming International Congress, doubtless some interesting facts will be brought out. Meanwhile, Dr. Marcel Baudoin, of Paris, has just published a description of what he terms a new (and safe) method of administering chloroform, by using small and continuous doses.

In a recent discussion at the Academy of Medicine on the accidents due to anæsthetics, Dr. Laborde endeavored to demonstrate experimentally, at the tribune of the Academy, that the beats of the heart were immediately arrested for two or three seconds when the cork of a bottle containing chloroform was placed under the nostrils. This phenomenon is not produced with the bichloride of methylene, but it is produced with ether, although less markedly than with chloroform. Professor Verneuil thought that laboratory experiments could not in any way throw light on the causes of death by chloroform, in man the most frequent being syncope.

News of the Week.

The Retirement of Surgeon-General John Moore, U. S. A.—During the present month Surgeon-General John Moore will reach the age limit of retirement and his successor will be appointed. Surgeon-General Moore has filled a career of over thirty-seven years in the army, having been appointed Assistant Surgeon from his native State, Indiana, in 1853. He passed regularly through the grades, served with distinction during the war, receiving the brevet of Lieutenant-Colonel for gallant and meritorious services during the Atlanta campaign, and that of Colonel for faithful and meritorious services during the war, and became the head of the Medical Department on November 18, 1886. At that time he had hardly been considered one of the leading aspirants in the contest for the place of Surgeon General, but his professional ability and army record were indisputable, and he was passed over the heads of some seniors. The ranking officer in the Medical Department is Colonel Jedediah H. Baxter, Chief Medical Purveyor. He began his military service in June, 1861, as surgeon of the Twelfth Massachusetts Infantry, and received the brevets of Lieutenant-Colonel, and Colonel of Volunteers, and of Colonel in the regular army, for faithful and meritorious services in the war. After its close he was appointed to the regular service from Vermont, his native State, with the high rank of Lieutenant-Colonel and Assistant Medical Purveyor, and with this start he achieved his present rank of Colonel and Chief Medical Purveyor sixteen years ago. Since then he has seen juniors promoted over him to the head of the department; but this fact was no reflection on his ability, as the officers thus preferred had served in the army much longer than he. In the present instance, also, the five other officers in the department who have the same rank of Colonel have been a very long time in the service. Surgeon Charles Sutherland entered it in 1852, from Pennsylvania, and reached his present rank in 1876. Assistant Surgeon-General Charles Page entered it in 1851, from Virginia, and reached his present grade in 1887. Surgeon Basil Norris, who is generally regarded as one of the chief competitors of Colonel Baxter, received his commission as Assistant Surgeon in 1852, being an appointee from Maryland, and reached the rank of Colonel in 1888. The two remaining surgeons, Colonel Edward P. Vollum, and Colonel Joseph R. Smith, were appointed in 1853 and 1854 respectively, both from New York, and reached their present grade last year. All of these officers received brevets for war service. Surgeons Sutherland, Norris, and Smith those of Lieutenant-Colonel and Colonel, and Assistant Surgeon-General Page and Surgeon Vollum, that of Lieutenant-Colonel. The reports of Colonel Smith were for superior ability and excellent management of the affairs of his department and meritorious services and devotion to the sick during the prevalence of the cholera at Little Rock. As the entrances of the first four of these officers into the service were all within less than two years of each other, so their retirements come close together, that of Colonel Vollum next year, that of Colonel Norris the year after, and those of Colonels Sutherland and Page in 1893. Colonel Smith does not retire until 1895, and Colonel Baxter not until 1901. Of course, the President is not compelled to select the Surgeon-General from among the Colonels. He might even go among the Majors, or lower if he chose.

Professor Jolly, of Strassburg, has been appointed to the Chair of Mental and Nervous Diseases in the University of Berlin, which has been vacant since the death of Professor Westphal.

Professor E. Ray Lankester has been elected Deputy Linacre Professor of Human and Comparative Anatomy at Oxford University.

Medical Education of Women.—A scholarship of the value of £100, tenable at the Edinburgh School of Medicine for Women, has been offered by the National Association, founded by the Marchioness of Dufferin, and is to be open to ladies desiring to fit themselves for the practice of medicine in India in connection with the National Association.

The Liston Victoria Jubilee Prize has been awarded to Robert Lawson Tait. It was open to all fellows and licentiates of the Royal College of Surgeons of Edinburgh, for the greatest benefit done to practical surgery by any of these during the triennial period ending June 20. 1890.

The International Congress of Hygiene.—The Prince of Wales has accepted the post of President of the International Congress of Hygiene, which will be held in London in 1891. He has fixed August 10th as the probable date at which he will open the Congress.

The Congress of the French Association for the Advancement of the Sciences will be held at Limoges from August 7th to 14th. Undoubtedly it will attract many French physicians that might otherwise have attended the International Congress at Berlin. A special feature in the proceedings will be a discussion on influenza, which the organizing committee is striving to make as thorough as possible.

The Enlargement of the New York Cancer Hospital.—The male pavilion of the New York Cancer Hospital (106th Street and Eighth Avenue, New York) will soon be completed and ready for occupancy. Heretofore the institution has restricted its benefits to females, accommodating seventy patients. The male pavilion, upon the same plan, will have an equal capacity, making that for the entire hospital one hundred and forty.

Since the construction of the new buildings was begun, several additions have been made to the hospital fund in the form of contributions. Among these were $5,000 from Mrs. C. P. Huntington, $5,000 from an anonymous friend through Dr. Cleveland, and $4,000 from Mrs. Susan M. Edson. The managers say, however, that the annual expenses are still $25,000 in excess of the income from all sources, and that contributions to the endowment fund will be necessary to make the work of the institution as effective as it should be. The charge for a bed in the wards is $7 a week, and for a private room $20 a week, but free patients are received and treated with as much care as those who pay. The actual cost of boarding and treating a ward patient is $350 a year, showing that there is no surplus from even those who can afford to pay the charges. This is the only hospital in the world devoted exclusively to the treatment of cancer cases, and deserves the support not only of the wealthy laymen, but the hearty endorsement of the profession. Patients are admitted from every part of the country on a physician's certificate of the nature of the disease.

Crowds of Doctors Everywhere.—Those who are interested in reading the names of passengers across the Atlantic, must have been struck by the excessive number of medical men on the lists of our ocean steamers. But in spite of this exodus, all our inland watering-places, all our mountain and sea-shore hotels, all summer resorts where more than ten families may be expected to flock together, have retained their undue proportion of physicians. It will soon happen that the medical fraternity will have only doctors and their families for patients. Professional charity will then have reached its high-water mark, and "doctor's bills" will be but a memory of the past.

Dr. Brieger, whose name is favorably known for his original work in bacteriology and general pathology, has been appointed Extraordinary Professor in the University of Berlin.

The Oldest Living Hospital Graduate.—As far as can be learned, the oldest living ex-hospital interne is the venerable Dr. Henry I. Bowditch, of Boston, who served on the house staff of the Massachusetts General Hospital in 1829. Dr. John L. Vandervoort, who has served as librarian at the New York Hospital for more than two-score years, was Junior Walker in that institution in 1831, and house physician in 1832 and 1833.

A French Physician sent to Germany to Study the Nose.—Dr. E. J. Moure, Lecturer on Laryngology at the Bordeaux Faculty of Medicine, has been commissioned by the French Government to study the arrangements for treating diseases of the throat, nose, and ear, and the provisions for teaching these specialties in Germany.

Professor Mikulicz has been called to the Chair of Surgery at the University of Breslau.

We are a Pretty Big Nation.—Approximate computations place the total population of the United States between 64,500,000 and 65,500,000 inhabitants.

The First Annual Congress of Psychological Medicine, which begins at Rouen on August 4th, will probably last four days. In addition to the communications which have been promised, the lunatic asylums of the Department of Seine Inférieure will be visited, and the two following questions will be discussed: 1. The Relations of General Paralysis and Syphilis. 2. The Proposed Reform of the Law of June 30, 1838.

Typhoid Fever at Milan.—Typhoid fever, diphtheria, and scarlatina have appeared in force over a great part of Milan, but especially in the quarter of the Porta di Genova. The health of the city is more than usually compromised. The water-supply is clearly to blame for this state of things, so discreditable to an industrial centre boasting the wealth and enlightenment of the Lombard capital. Wells sunk in the subsoil of the level plain on which it stands become easily impregnated with organic impurities, and make the drinking-water supplied from them to the hotels and *pensions* a ready source of disease and death. Milan, on the admission of her best sanitary engineers, can avert this danger by bringing her water-supply from the neighboring Alps by means of an aqueduct; and no satisfactory reason has yet been put forth for the postponement of so urgent an undertaking.

According to information which appears in another column, the city of Birmingham, Ala., might with advantage follow the advice given to Milan, in respect to sanitation and a proper supervision of her water-supply.

Hæmaturia and Garden Rhubarb.—A correspondent of *The Lancet* writes concerning a little "local epidemic" of kidney complaints. The majority of the patients had frequent micturition, several of them had hæmaturia, and all of them complained more or less of pain in the loins and of general indisposition. After some consideration it was found that they were eating delicious rhubarb tarts; indeed, several of the patients were indulging in them morning, noon, and night, and, in addition, they were drinking hard water rather copiously, as the weather was very hot. With these facts before him, the production of the epidemic was quite easy of explanation. The rhubarb supplied plenty of oxalic acid, and the hard water an abundance of lime; so countless minute calculi of oxalate of lime, easily seen in the urine with a magnifying glass, were manufactured in the system, and caused the symptoms complained of. From that day to this he has been on the lookout for kidney complaints in the spring and summer, and he frequently finds them and the cause of them. Gooseberries, when eaten freely, often produce symptoms similar to rhubarb, and so do acid unripe apples. In the production of these kidney affections lime sees to be an almost necessary ingredient.

Sir Morell Mackenzie, who it was expected would lecture in this country next October under the management of J. B. Pond, has sent word that his health will prevent him carrying out his engagement. He offers to come next year, however.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 15, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

DR. LOUIS L. SEAMAN read a paper on "The Ausculta tory Percussor" (see p. 64).

Spinal Surgery: A Report of Eight Cases.[1]—DR. ROBERT ABBÉ read a paper on this subject (see p. 87).

The patients in Cases V. and VII. were presented to the Academy.

DR. JOHN A. WYETH said that he had been struck with one feature of Dr. Abbe's cases, and especially those of traumatic origin, and that was the location of the injury to the spinal cord. In three traumatic cases the injury was in the vicinity of the eleventh dorsal vertebra, and this was also the case in two cases of his own; in one of them the trouble being at the eleventh dorsal vertebra, and the other at the twelfth. This was the portion of the spinal column which was most exposed to direct violence.

In the surgery of the spine he thought it would be well to divide the cases into several categories, and in his own mind he had formulated the following classification. Under the first heading he would place all cases of compression by bone, dividing them into two classes—first, those in which the compression was gradual, as in Pott's disease, and second, those in which there was compression and more or less destruction of the cord from sudden violence. Under the second heading he would place the cases of compression by tumors, dividing the latter into intradural and extradural tumors. In our present stage of knowledge he thought the cases where there was destruction of a portion of the cord were practically incurable, and this seemed likely to continue to be the case unless it should become possible to remove the body of a vertebra, and thus enable the surgeon to bring together the healthy portions of the cord situated above and below the part that was destroyed. This was an operation, however, which he would not care to undertake or to witness at the present time. As to tumors of the cord, those which were intradural were naturally more dangerous than those which were outside the dura, and in them the chance of recovery was less assured.

Dr. Wyeth then gave the histories of the two cases of fracture of the spine in which he himself had operated. In the first the fracture was situated at the twelfth dorsal vertebra, and there was complete recovery after the operation, notwithstanding the fact that the patient had been paralyzed for more than two years previously. In the second case the fracture was at the eleventh dorsal vertebra. At the seat of trouble the cord was found to be somewhat flattened, and there was considerable inflammatory lymph binding the cord very firmly to the dura. The adhesions behind the cord and dura were broken up by the finger. The injury had been received on September 16th last, and the operation was performed seventeen days ago. As a result of the operation sensation was immediately recovered down the entire lower extremities. Motion, also, was restored to the two big toes, but up to the present time the paralysis of motion had been relieved only to this extent. From what he had seen and read he could not doubt but that in many cases of compression, and especially those of traumatic origin, the patients could be restored to usefulness by means of operative interference.

DR. A. P. GERSTER said that an obstacle to the restoration of function in cases in which the spinal marrow was divided was the area of cicatricial tissue lying between the separated ends. He did not know whether or not experiments had been made on animals to find out whether, if the divided ends could be united, the functions would reappear; but, from experience met with in the case of divided nerves it seemed probable that it would. The matter was certainly worthy of investigation, and even desperate operative measures, he thought, were justifiable in such cases on account of their hopeless character. The technical difficulties of bringing together the divided ends of the cord could no doubt be overcome by practising the procedure on the cadaver. Furthermore, he did not see why the extreme measure referred to by Dr. Wyeth, of removing an entire vertebra, should not be resorted to under certain conditions. If he thought such an operation would enable him to restore the functions of the lower portion of the cord he would not hesitate to perform it, provided he should first have demonstrated its practicability by experiment. He would not think of undertaking it, however, until it had been shown upon animals that such a restoration of function was possible by the uniting of the several ends of the cord.

His personal experience in spinal surgery had not been extensive. Eleven years ago he had had at the German Hospital a case of new growth involving five of the vertebræ and causing paraplegia. The patient was admitted with a large tumor occupying the median line of the back, and he attempted the removal of the growth. It had originally, no doubt, been sarcomatous in character, and it had become largely infiltrating. He succeeded in removing the greater portion of it, and in doing this he had to scrape some of the mass from the dura. The latter had become softened, and it gave way at some points, allowing a considerable amount of cerebro-spinal fluid to escape. The immediate results of the operation were very satisfactory, sensation and motion in the paralyzed extremities both becoming much improved. Later, however, a relapse occurred, and the case terminated fatally.

A second case of his had a more fortunate result. It was one of vertebral tuberculosis of long standing, and the patient was a lad fourteen years of age. He had been admitted to Mount Sinai Hospital, and was under treatment since December, 1888, by plaster jacket with fenestra. In May, 1889, rapidly increasing paraplegia set in; commencing with loss of sensation and gradual waning of muscular power, so that within ten days complete paralysis was established. The rectal and vesical functions also became sluggish, requiring local measures for evacuation. On May 24th it was decided to explore the local state of affairs. The laminæ of the sixth and seventh dorsal vertebræ were removed by the chisel and mallet, and an extensive extra and subdural abscess was evacuated. Widespread confluent caseation of the soft tissues adjoining the intravertebral focus was found, in which caseous masses were imbedded in the roots of the motory or sensory nerves on both sides. The transverse processes of the fifth, sixth, seventh, and eighth thoracic vertebræ on the right, and those of the fifth, sixth, and seventh on the left, were found carious and partially necrosed, and the pertinent costo-vertebral joints destroyed. Consequently, these transverse processes were removed, as well as the heads of the respective ribs. The bodies of the sixth and seventh vertebræ were also much disintegrated, and their broken-down constituents were gouged away. The operation was well borne, and the large wound, which was packed with iodoform gauze, filled up rapidly and healed kindly, but no immediate improvement of the paralytic symptoms was observed. In the following August, however, the power and functions of the lower extremities were re-established, and this restoration took place in the short space of about ten days. By massage, faradism, and active movements the muscular power was so enhanced that the patient was able to support himself without external aid by October; while in December he was discharged with a slightly discharging sinus of the dorsum and apparently not more of a kyphos than he exhibited on admission.

DR. MORRIS said that experiments such as Dr. Gerster had referred to had been made on animals, but no very satisfactory results had as yet been obtained. The testimony showed that ascending and descending degenera-

[1] In charge of the Section on Surgery.

tion followed division of the cord, but it seemed to him that if, in case of its accidental severance, we could get the two ends of the cord together within a few hours we might hope for a restoration of function. The ends of the cord it was found after division did not retract very far, for the reason that the spinal nerves are given off at short intervals. It seemed probable that we would not have to remove a vertebra; and if this were to be attempted the most troublesome feature that would be encountered would be the crowding together of the spinal nerves. The danger of such a procedure need scarcely be taken into consideration, since the cases in which it might be thought of were of such a very desperate character.

He had at present under his care a boy, eleven years of age, who had been shot with a 22-calibre bullet in the line of the tenth dorsal vertebra, with the effect of producing paralysis of the lower portion of the body. He first saw the patient seven days after the injury, and he immediately cut down and opened the spinal canal. He removed an articular process which was found pressing upon the cord, and this was at once followed by improvement in both sensation and motion. In the right leg the recovery was now almost complete, but in the left the paralysis still continued to a very considerable extent. He was not able to find the bullet, which had no doubt lodged somewhere in the spinal cord.

Dr. Reginald H. Sayre urged immediate operative interference in recent traumatic cases. There were many cases of paraplegia resulting from Pott's disease, he said, in which a cure could be effected without resorting to operation. Cases in adults, however, which did not yield to systematic treatment directed to the Pott's disease within twelve months he thought might very properly be looked upon as suitable cases for operative interference.

Dr. B. Sachs said that up to the present time the results that had been obtained in spinal surgery were not especially gratifying. As a neurologist he thought that surgeons should select their cases for operation with more care than they had hitherto done. With Dr. Sayre, he believed that recent cases presented the best opportunities for operative interference. If the cord were separated into two parts, however, there was, in his opinion, not much hope of accomplishing anything. In cases in which the symptoms had become less marked than they had been at first, as was the case in one of Dr. Wyeth's cases, in which he was the medical consultant, there was a much better chance for success for operation, since the amelioration indicated that there had not been a total destruction of tissue. Dr. Abbé, he thought, was deserving of great credit for demonstrating that such good results could be obtained in tuberculous cases as were presented in the patient which had been exhibited. Formerly the opinion had been held that no operation ought to be undertaken in tuberculous cases.

He had been a little puzzled to understand why, in some of the cases reported by surgeons, so many laminæ had been removed. As a rule, he believed this was entirely unnecessary, since, if proper care were observed in diagnosis, the lesion could ordinarily be located with very great accuracy. Operations on the spine for the relief of neuralgic trouble seemed to him to be the most objectionable in the whole range of spinal surgery. Judging from the results obtained by Dr. Abbé in the two cases he had reported, no improvement whatever was to be expected from them; and, in any event, this was certainly a very radical method of attacking neuralgias. It was to be remembered that pain was not the only symptom that was likely to result from trouble involving the posterior spinal roots. Vasomotor disturbances especially, as well as neuralgia, would be apt to follow. As these two cases showed, unless we had good reason to infer the existence of organic disease of the posterior spinal roots, it would not be well to interfere in this way.

Dr. Abbé closed the discussion in regard to neuralgia. He said that no sane man would think of operating in ordinary cases. In the two patients upon whom he had operated, however, the trouble was so exceedingly aggravated, and so utterly unamenable to all other remediable measures, that the procedure seemed to him entirely justifiable as a last resort. That such operations might be attended with success was shown by a case in England, reported by Bennett. It was one of sciatic neuralgia, and though the patient unfortunately died of apoplexy twelve days after the operation, from the time of the latter there was complete freedom from the pain, which before had been so constant and so excruciating. In his own two cases he wished it to be distinctly understood that the character of the pain experienced was entirely altered after the operation. In both patients he believed there had been a hysterical element, although he had tried to eliminate this as far as possible. Both were also still taking morphia largely, and such cases could not be depended on. Moreover, it so happened that both of these men were trying to get pensions on the ground of their disability from the pain. While, therefore, he really believed them to be genuine sufferers, he was not at all sure about the matter.

In fractures of the spine he believed the operation should very rarely be done. He was not positive, however, that restoration of innervation to the lower segment of the cord could not be successfully accomplished after further experiments upon animals had been carried on. But to bring the divided parts of the cord directly together again he thought could only be accomplished by removing one of the vertebræ, and this he believed could not be done without destroying the patient's life.

Dr. Thomas M. Manley briefly referred to a number of cases of fracture of the spine which he had met with in the surgical service of the Harlem Hospital.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 26, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Etiology of Cancer of the Cervix Uteri.—Dr. C. N. Dowd presented a specimen taken from a cauliflower-like growth on the cervix uteri of a patient, twenty-two years of age, who had given birth to a child two years before. The cervix was much enlarged and lacerated bilaterally. The cauliflower-like excrescences were abundant, and many of them were so brittle that they could be pulled off by the forceps. The surface bled freely on irritation. In making a diagnosis the following points were to be considered: The appearance of the growth was that of a carcinoma, but it had not involved the vaginal walls; there was none of that peculiarly offensive sanious discharge which is so characteristic of cancer of the uterus; the patient was but twenty-two years of age, and did not present a cancerous cachexia. Hence the probabilities were decidedly against cancer, yet the possibility of a malignant new-growth not far advanced, which had started in granulation-tissue was to be considered, and microscopical examination was necessary to decide the question. This was made on a section cut from the granulating surface, and on one of the excrescences which was pulled away. At the edge of the section there were round and elongated cells, packed closely together, which in spots looked very much like sarcomatous tissue. There were also a few polynuclear cells resembling giant cells. There were ill-defined blood-vessels and a moderate amount of connective tissue; at a distance from the surface this connective tissue was more abundant. One could not assert positively from the microscopical examination whether this was granular tissue taking on the type of sarcoma, or not.

The relation between granulating lacerated cervix and malignant growth is one of very great importance from a practical standpoint. On the one hand unnecessary operations are performed, and on the other cases of cancer are allowed to develop until no operation can be of any

use. The concensus of opinion certainly is that there is a predisposition to malignant growth in a lacerated and granulating cervix. Dr. Dowd presented some statistics, taken from the United States Census Report, showing that of all deaths among women two and a half per cent. were from cancer, and that in one-third of all cases of cancer the disease was situated in the uterus. The statistical tables also showed that parturition had a decided effect—direct or indirect—upon the development of cancer of the uterus.

Dr. H. J. Boldt thought that the specimen under the microscope closely resembled carcinoma; and the clinical history, which was often of still greater importance in these cases, tended to confirm the indications of malignant disease.

Cancer of the Liver.—Dr. Hodenpyl presented a specimen of cancer of the liver removed from a woman about fifty years of age, who had entered St. Francis' Hospital suffering from an abdominal tumor on the right side. An exploratory incision was made, but further operation was inadmissible. The autopsy showed a large cancerous growth in the lower portion of the right lobe of the liver. The gall-bladder was filled with calculi, and the fundus appeared normal in thickness; but the other extremity was completely ulcerated away. The intestines, stomach, and peritoneum were firmly adherent to the under surface of the right lobe of the liver, and the large intestine opened directly into the large cavity seen in the specimen.

Primary Cancer of the Uterus.—Dr. J. H. Linsley presented a report of a case of carcinoma, and exhibited under the microscope sections of the growth. The specimens were removed from the body of a married woman, forty-five years of age, who had had one child after an easy labor, and several miscarriages, always between the second and fourth months, but these never affected her health, which was always excellent. About two months ago she noticed the abdomen was growing larger, and she had occasional pain. At the same time she began to lose appetite and strength. Latterly she had had swelling of the left leg and considerable dyspnœa. She was admitted to St. Luke's Hospital where laparotomy was performed by Dr. Abbé. The operation was performed under chloroform, as the woman was too weak to take ether. An incision was made in the median line down to the peritoneum. This was picked up with forceps and nicked, and Chamberlain's tube being introduced, three-fourths of a large bucketful of yellow, glairy, albuminous fluid was withdrawn, much being left in the abdomen. Examination by the finger showed cysts of various sizes scattered here and there, and a papillomatous growth was felt in the anterior abdominal wall, involving part of the bladder. The peritoneum was covered with small tubercles, one of which was cut off for examination. The wound was then closed, and an antiseptic dressing applied. The patient complained of no pain until toward the end of the operation. After this operation the condition remained about the same, the patient gradually grew weaker, and died three months later.

Autopsy.—The peritoneum was thickened and roughened everywhere, and adhesions were very numerous. There was one large mass, consisting of omentum and folds of intestine, adherent to the peritoneum directly beneath the umbilicus. The intestines were bound down everywhere by firm adhesions, and on their surface were many small, hard, whitish nodules. The right lobe of the liver was deeply scarred, its capsule was thickened, and on its surface were several hard nodules about the size of a pea. The pancreas appeared to be studded with whitish nodule or deposits of new formation. All the pelvic organs were so bound down that they were hardly distinguishable. The surface of the peritoneum was covered everywhere with new formation of the same appearance as that already noted. The mucous membrane of the rectum was normal in appearance, except at one point over the brim of the pelvis, where there was an ulcer two-fifths of an inch in diameter. In the floor of the bladder there were numerous deposits of new formation, and the wall of the vagina was also infiltrated, in places, with the same growths. The outline of the body of the uterus was not distinguishable, but on following its cavity it was found to be bound down to the rectum, being sharply retroflexed, and infiltrated with the new formation. Numerous cysts were found on either side of the body of the uterus, the larger of which were one and a quarter inch in diameter, and corresponded to the location of the Fallopian tubes. The ovaries could not be distinguished.

Examination of the new-growth under the microscope showed it to be carcinoma. It was characterized by an abundant stroma of connective tissue with alveoli of various sizes, some of which were quite large and were filled with epithelium. The epithelium was small, flat, and cuboidal in shape, and distinctly nucleated. The growths examined in different parts of the organs where this new formation was seen exhibited the same structure. In various organs the walls of the blood-vessels were seen to be thickened. The seat of the primary growth was undoubtedly the uterus.

Metastatic Carcinoma of the Stomach.—Dr. John S. Ely presented some specimens illustrating carcinoma of the right testicle, with metastases in the lungs, stomach, and falx cerebri. The patient was a man, thirty-nine years of age, who had entered St. Luke's Hospital on account of a painful tumor in the right testicle. He had been ruptured for about twenty years, and had worn a truss all that time, and the previous winter had procured a new one, which had fitted poorly and had caused a good deal of irritation and discomfort. About three months before admission to the hospital he had noticed that the testicle was enlarged, rather hard, and tender, and a little later he discovered a hard mass extending upward and outward from the testicle, to which it seemed to be attached. The sac of the hernia was above this mass and was reducible. The testicle was removed, and was found, on microscopical examination, to be cancerous. Two months after leaving the hospital the patient began to have pain in the right inguinal region, and soon a tender tumor was discovered in this place. On examination the tumor was found to extend upward as far as the level of the anterior superior spinous process of the ilium, and inwards to the external border of the rectus abdominis muscle. Laparotomy was performed by Dr. B. F. Curtis, but a mass of such considerable size was found lying against the lumbar vertebræ that it was deemed inadvisable to attempt the removal of any of it. About a month later the patient died. At the autopsy numerous nodules were found scattered throughout the lungs, varying in size up to one and one-half inch in diameter, most of them white with reddish spots, and circumscribed, though in the lower portion of the left lung there was much diffuse infiltration of white tissue. The bronchial glands contained some cheesy nodules. In the cardiac portion of the stomach, near the greater curvature, was a mass resembling the other tumors, which was apparently in the submucous coat. This was found on section to consist of two small nodules. There was a mass of nodular growths along the psoas muscle and vertebral column from Poupart's ligament to the diaphragm. There were also a few isolated nodules along the dorsal vertebræ. The mass in the pelvis enveloped the large vessels to a great extent, and in the lower portion of the inferior vena cava, and in the right common iliac vein there were firm clots, somewhat adherent in spots, soft and gray. A few small nodular growths, some of which appeared to be ulcerated, projected into the lumen of the vena cava. In the falx cerebri, about one and one-half inch from the anterior end, was a tumor one inch in diameter, irregularly nodular, and of encephaloid consistence, reddish exteriorly, but gray in the centre. Microscopical examination of all these neoplasms showed them to be the same in structure, the tumors being recognized as medullary or encephaloid carcinomata.

Irritation caused by the truss or by the non-descent of

the testicle may have had something to do with the development of the cancer, which spread along the pelvic and lumbar lymphatics. Metastases in the stomach were very rare; he had only been able to find twenty-four such cases mentioned. The case was a striking verification of the statement made years ago by Virchow, that malignant tumors occurred least frequently, metastatically, in those organs in which they are most common as primary growths. Metastases of the dura mater and falx cerebri are quite unusual, only twenty-five cases of metastasis of the whole dura mater being found in a series of three hundred and sixty-six cases of primary carcinoma of the mamma. An examination of the lungs showed numerous arteries filled with clots, many of which contained large numbers of epithelial cells similar in every respect to the epithelial cells found in the tumors throughout the body; and similar to the epithelial cells which were visible in the specimen showing a nodule in the inferior vena cava. This nodule showed a rupture of its walls on the upper side, and over this was a small clot.

DR. DOWD said regarding the question of irritation as a factor in the production of cancer, that it was interesting to recall the statistics of Siegler, which showed that out of a large number of collected cases, from seven to fourteen per cent. could be traced to irritation. Wolff also gave the statistics of a series of cases of carcinoma occurring in one of the Berlin clinics during a period of eleven years. Out of about six hundred cases, fourteen per cent. gave a history of traumatism.

DR. B. F. CURTIS thought there could be no question about the greater liability of the undescended testis to malignant disease; and when the testis was situated near the ring, this was particularly noticeable. But in this connection it was curious to note how rarely malignant growths were found in connection with epididymitis, hydrocele, and other inflammatory conditions, in which the testicle was exposed to violence.

Cancer of the Breast.—Dr. Curtis then presented a series of large sections of carcinoma of the breast, made through the entire gland by means of the special microtome used for cutting similar sections of the brain. The specimens had shrunken about one-third in the hardening process. The sections had been stained with various agents, such as carmine, hæmatoxylin, and saffronine. The first section showed the growth occurring in a very stout woman, in whom there was a layer of fat about one inch thick between the gland and the skin. The second section showed the growth in the centre of the gland, spreading through the nipple into the skin. As was usual in cases involving the skin, the recurrence in this patient was very rapid. The third specimen was from a woman of about forty-five years of age, who had never had any children, and in whom the gland was quite small. The degeneration had spread through the gland and into the nipple, but the mass was entirely distinct from the nipple. The patient died from early metastasis in the liver. The fourth specimen showed the involvement of the nipple; and the fifth slide showed a specimen of cystic carcinoma. Dr. Freeborn had rendered valuable assistance in the preparation of these sections.

Primary Cancer of the Gall-Bladder.—DR. FRANK FERGUSON presented specimens removed from a woman sixty-seven years of age, who was admitted to the New York Hospital in a moribund condition. At the autopsy, the entire gastro-intestinal tract was found to be free from cancerous growths. The side of the gall-bladder next to the liver was thoroughly infiltrated with cancer, the thickest part of the growth in its walls being elevated one-fourth of an inch above the mucous membrane. From the neck of the gall-bladder to the common duct, the duct was normal. The gall-bladder contained two calculi of moderate size, triangular in shape, and having fairly sharp angles. The liver extended in the median line to the umbilicus, and on the right side to the crest of the ilium. Its surface was nodular, and the organ itself contained large cancerous masses, such as were usually regarded as secondary to cancer in the gall-bladder. Dr. Ferguson considered that the cancer of the gall bladder was primary, for the following reasons: 1. A number of cases of primary cancer of the gall-bladder had been reported. 2. Primary cancer of the liver was extremely rare—he had not met with a single case in his own experience. 3. In cases which had been conceded to be primary, the growth had occurred as one or two large masses confined to one portion of the liver. 4. The growth in the present case was continuous with the mucous membrane of the gall-bladder. 5. In accordance with the law already alluded to, viz.: that those organs which were commonly the seat of primary cancer were very rarely the seat of secondary generalization.

Intestinal Diverticula.—The case was also of interest as presenting the somewhat rare condition of intestinal diverticula. These diverticula were of various sizes, extending from the mucous membrane through the muscular wall of the large intestine, and containing masses of hardened fæces. There was a cavity in the retro-peritoneal tissue which established communication between the gut and the peritoneal cavity, and gave rise to a general peritonitis. Some time ago a similar case had been presented by Dr. Hodenpyl.

DR. H. M. BIGGS said that about two years before, Dr. Ferguson had presented a specimen of this sort, and had commented on the rarity of its occurrence in his own experience. The speaker had given the matter careful attention since that time, and had observed four cases—one in which there was perforation, and three in which this condition did not exist.

DR. FERGUSON replied that he always examined the large intestine carefully, but had only been able to find six examples of the condition in question. Even quite recently, the literature showed only a very few recorded cases.

Hemorrhage from the Supra-Renal Capsule in very Young Children.—DR. HODENPYL said that Dr. Prudden had recently presented a case of hemorrhage from the supra-renal capsule in a very young child; and he desired to add another case showing some peculiar features.

The child from which his specimens were taken was born after a perfectly normal labor, and appeared to be doing well up to a few hours before death, which occurred on the third day, after sudden symptoms of collapse. The autopsy showed the abdominal cavity distended with blood, which had come from a rupture of the right supra-renal body. The remarkable feature of the case was that the supra renal body had penetrated the under surface of the liver, and stripped up Glisson's capsule for a considerable distance. There was also an infarction of the lung.

Abscess of the Spleen.—Dr. Hodenpyl also presented a case on this subject. The specimen was removed from a man about forty years of age, who died with symptoms of chronic Bright's disease. The kidneys showed the changes of the advanced stages of this disease. The spleen was quite large, and surrounded by a mass of thickened fibrous tissue and adhesions, in which was a sacculated abscess. In the lower part of the organ, the spleen pulp had broken down, forming a cavity which was filled with fetid pus. There was no evidence of infarction, the brain, lungs, and heart were normal, and the speaker was at a loss to account for the condition.

Pachymeningitis Interna Hemorrhagica.—DR. WILLIAM P. NORTHRUP reported three cases of this affection as supplementary to the case presented by him at the last meeting of the Society. They were taken from the records of the Foundling Asylum. The first case was that of a girl four years and seven months old. The child was returned to the asylum in midsummer in miserable condition, with a diagnosis of tuberculosis. It improved later, then had whooping-cough, and suffered from diarrhœa characterized by a very offensive odor, and after this failed and finally died after three days of repeated convulsions. On autopsy its body was seen to be ex-

tremely emaciated. The brain was normal, pia mater œdematous. The dura mater lining the left half of the calvarium was covered with an exudate as thick as blotting-paper, opaque, mottled-red, dark and pale. The right half was covered with a thin pellicle which could easily be scraped from the dura mater, and when placed under the microscope was found to contain an abundance of newly formed blood-vessels with thin walls. The lungs were adherent, œdematous, and the seat of chronic broncho-pneumonia. There were no tubercles in any part of the body.

The second case was that of a male child, four months and nineteen days old, whose chief symptom was drowsiness. It "looked sick," but physical examination gave a negative result, and no diagnosis was made. It died after a prolonged series of convulsions. At the autopsy the anterior fontanelle was seen to be widely open, and the frontal suture was also open down as far as the nasal eminence. There were no signs of inflammation nor of external injury. The dura mater investing the inner surface of the posterior half of the skull from the base to the apex, was covered with a pellicle which could be easily scraped from the surface and which showed under the microscope newly formed vessels with thin walls, dotted everywhere with points of hemorrhage. No other lesions of moment were found in the case. There were no tubercles and no evidences of meningitis.

The third case was that of a male child, nine months and nineteen days old. The child was returned to the house in a wretched condition, and died after repeated convulsions. At the autopsy it was seen to be markedly rachitic. There was a well marked exudate upon the entire surface of the brain from the vertex to the base; the ventricles were dilated; the medulla was normal. The dura mater in the middle fossa and inner surface of the temporal region was covered with a fine pellicle containing newly formed vessels and punctate hemorrhages. This pellicle was easily stripped from the inner surface. There were no other lesions.

In addition to these four cases the records of this Society, Dr. Northrup said, furnish at least two more; one a child twenty months old, having meningitis and pachymeningitis, presented by Dr. L. Emmet Holt, in 1887; the other a child of eighteen months, presented by Dr. S. J. McNutt within the past year. Pachymeningitis is "characterized by the formation of layers of delicate connective tissue with numerous very thin-walled blood-vessels from which the blood is prone to escape" (Delafield and Prudden). As there had been some doubts expressed as to the correctness of the diagnosis in the case presented by him at the last meeting, he desired to have the specimen referred to the Committee on Microscopy. He had met with only four cases, all under two years of age, in an experience founded upon fifteen hundred autopsies.

The Society then went into executive session.

Stated Meeting, April 9, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Report of the Committee on Microscopy.—Dr. John S. Ely, from the Committee on Microscopy, reported that the specimens submitted by Dr. Northrup, at the last meeting of the Society, presented the appearances of pachymeningitis interna hæmorrhagica.

Small and Large Round and Spindle-cell Sarcoma.—Dr. Joseph H. Linsley presented a specimen removed from the body of a man, aged fifty-three, giving the following history: The patient was a German, who was admitted to the Post-Graduate Hospital, under the care of Dr. Kammerer. The tumor was first noticed about thirteen years ago, but it remained quite small (the size of a tea-cup) until about four weeks before admission, at which time it began to grow very rapidly. For the past two weeks it had caused distressing dyspnœa, increased by exertion and becoming rapidly more serious every day. The patient became emaciated, had dysphagia and distressing periods of coughing. From the location of the tumor it was undoubtedly of the thyroid gland; it measured perpendicularly five inches, extending from two inches above the sternum to three inches below the mental process; the transverse measurement carried over the cricoid was six inches; the skin was raised from its normal level about two and one-half inches over the centre of the tumor. The shape was symmetrically round except that from the right upper portion a lobe extended upward to near the angle of the jaw, while on the left side there were two inches between the border of the tumor and the corresponding angle. The skin covering the tumor had a normal appearance. The tumor was hard and somewhat nodular, not painful nor tender on pressure. Several introductions of the exploring-needle gave no evidence of its being cystic. While the tissues were not flabby, there was still a tendency to sag. The patient was put under chloroform and died during the operation on the table. The tumor extended to the vertebral column and was very firmly bound down by adhesions; it weighed six hundred and fifty grammes. The heart weighed four hundred and thirty grammes. The edges of the aortic valves were much thickened, and their surfaces somewhat roughened. The muscular tissue of the heart was of a brown color. The upper lobe of the left lung was poorly aërated. On the surface, and scattered through the organ, were hard, white nodules, varying in size from that of a small pea to that of an English walnut. The lower lobe was poorly aërated and slightly œdematous. The apex of the right lung was completely infiltrated with these nodules, one of which measured about four centimetres in diameter, and was broken down in its centre. The middle lobe of this lung was deeply congested and œdematous. Projecting from the anterior surface of the lung was a fairly firm white mass, 3 ctm. in diameter. There were also many hard white nodules scattered throughout the lobe. The lower lobe was congested and œdematous, and contained a number of these nodules. On the surface of the left kidney were seen two hard nodules about one centimetre in diameter. In both kidneys the capsule was adherent, the surface was granular, and the markings fairly distinct. The mucous membrane of the stomach in general looked normal. Near the pyloric end was a hard white spheroidal nodule, 1 ctm. in diameter, the centre of which was depressed. In the lower part of the jejunum the gut was invaginated, though there was no obstruction. The mucous membrane of the colon was deeply congested. The lower part of the alimentary tract contained a large quantity of tarry material. At different places throughout the small intestine were found nodules and ulcers, varying in size from a pea to a silver dollar. The edges of these ulcers were somewhat raised above the surface of the mucous membrane, and their surface was nearly black. There seemed to be some increase in the connective tissue of the liver and a deposit of fat. On the anterior surface of the right lobe was found a small white nodule, ½ ctm. in diameter. The gall-bladder was normal and contained a small quantity of natural looking bile. The bladder contained a small amount of urine, and its wall was greatly hypertrophied.

Microscopical Examination.—The tumor was composed almost exclusively of small round, large round, and spindle-formed cells. There was a fibrous stroma, but it was not prominent, and the relation between it and the cells was most intimate. The vascular supply was abundant and the walls of the vessels thin. A considerable amount of granular matter, which stained poorly, was seen. The growth was a sarcoma. The alveola walls of the lungs were thickened and somewhat infiltrated with small round cells. A large area was seen where the structure of the lung was lost, its place being occupied by small and large, round and spindle-formed cells. Numbers of these cells were also seen in many of the air-spaces of the

lungs. In the kidneys a large area was seen extending from the cortical into the medullary portion of the organs, the structure of which was similar to that of the tumor. Very little of the normal structure of the spleen was seen in the sections examined. The greater number of the sections showed the presence in large numbers of sarcomatous cells. The interstitial connective tissue of the liver was increased, and areas composed of the same variety of cells before described were seen. Sections taken from the ulcers or nodules in the intestines showed the same sarcomatous structure. The villi were infiltrated with these cells, and a large growth of them was seen in the submucosa widely separating the muscularis mucosæ and the muscular coats. The blood-vessels were distended with blood, and the columnar epithelium covering the villi, in the neighborhood of the growths or nodules, were either very granular or wholly lost.

An Anencephalous Monster.—DR. JOHN S. ELY presented an anencephalous monster from the museum of the College of Physicians and Surgeons. The specimen also showed a certain amount of opening in the spinal column. There was absolutely no indication of any brain, all that was to be seen being some membranes with a little fluid beneath them. The speaker had seen four similar specimens within about four years.

Chronic Endarteritis.—Dr. Ely also showed some specimens removed from the body of a woman about fifty years of age. She had had the typical symptoms of chronic Bright's disease with contracted kidney. At the autopsy the kidneys were found to be extremely small and contained cysts, in some of which were to be seen arteries running through their walls. In the heart light spots were seen suggesting interstitial myocarditis. The lungs contained some brown induration. The liver was fatty and congested. There was chronic endarteritis generally distributed throughout the body. The point of special interest in connection with the specimen was to determine whether the kidney trouble or the endarteritis were the primary lesion.

Pachymeningitis Interna Hæmorrhagica.—DR. WILLIAM P. NORTHRUP presented another specimen, supplementary to those submitted at the two previous meetings, showing the lesions of pachymeningitis interna hæmorrhagica. The specimens were taken from the body of a child about one year old, who was sick about one month. When it first came under observation it had diarrhœa, a temperature of 104° F., was restless, and somewhat rigid. Apart from this it had no special cerebral symptoms. The diarrhœa improved, but the child continued fretful and had a moderate cough. There were at no time convulsions, paralyses, eye symptoms, nor tâche cérébrale. The child subsequently developed acute enteritis with a final temperature of 107° F., and died.

Autopsy.—The body was moderately well nourished; there was a slight rachitic rosary. There was moderate internal pachymeningitis with slight hemorrhage. One patch, more marked than any other, was situated at the left apex of the calvarium. A film made up of fine vessels could be easily scraped away. Aside from the patch at the left apex was a diffusely distributed delicate pellicle with fine vessels, the course of the latter being marked with punctate hemorrhages. The pia was œdematous and "wet," but was itself normal. The heart was normal. The bronchial lymph-nodes were enlarged, red, not tuberculous. Moderate congestion and consolidation of the posterior margin of both lungs, with scattered lobules of pneumonia and bronchitis. The mesenteric nodes were large and red. Peyer's patches were swollen and red, and there was an increase of mucus. Among the long bones examined, the lower end of the femur showed an irregular line of ossification.

The Society then adjourned.

The University of Louvain has added a course of medical ethics to the ordinary programme of professional study.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL NURSES AND THEIR WORK—GRAVE CHARGES AGAINST THE LONDON HOSPITAL—THE NATIONAL PENSION FUND FOR NURSES—DEATHS OF SIR EDWIN CHADWICK AND PROFESSOR W. K. PARKER—THE COLLEGE OF SURGEONS.

LONDON, July 12, 1890.

IN a recent letter I referred to some statements which had been made in the public press here regarding the unsatisfactory status, onerous duties, and inadequate pay of hospital nurses. The statements to which I referred were general ones, and no one hospital in particular was specified as deserving of censure in regard to its treatment of the nurses in its employ. The general allegations made, however, have now come to a distinct head as regards the largest metropolitan hospital (the London), for a series of definite charges have been made against the way in which the nursing arrangements have been managed. These charges have been made before the House of Lords' Select Committee on Hospitals, now sitting. Some of them, if fully established, are sufficiently serious. A former chaplain, several nurses, the matron, and the hospital secretary have already given evidence before the Committee. It is alleged that the number of nurses are inadequate for the work, and that in consequence they are overworked, and that many of them have suffered in health. The food was bad, and the drainage defective. Some of the wards were overcrowded, and on several occasions when Sir Andrew Clark—who strongly objected to overcrowding—visited the hospital, a number of patients in his ward were wheeled out, and half an hour after he had gone they were wheeled back again. One probationer stated that after being at the hospital only a fortnight she was put in charge of a tracheotomy case as special nurse. Probationers of much less than two years' service were sent out to private patients at good fees as thoroughly trained nurses. Complaints were also made of probationers and nurses having been dismissed on insufficient grounds and without proper notice. Other charges were also made besides those I have briefly summarized above. The matter is not yet fully threshed out, but it is only fair to say that some of the charges were strenuously denied, both by the matron and secretary. Some, however, were admitted. The matron denied that the nurses were overworked. For the actual hospital work there were two hundred and eighteen members of the nursing staff, and twenty-two ward-maids, who were non-resident. (The in-patients at the London Hospital number nearly eight hundred.) She had no knowledge of overcrowding of the wards. She had made a strong report to the House Committee in 1882, as to the food, and the result had been a gradual and great improvement. It was admitted that probationers were sent out to private patients as trained nurses. The matron had now (though only since last November), the power to dismiss probationers. The London Hospital is the largest in the United Kingdom, and is also one of the poorest; hence the importance of thoroughly sifting the present charges cannot be over-estimated.

A more pleasing incident to chronicle in connection with hospital nursing is the garden fête at Marlborough House, at which certificates were to be presented by the Princess of Wales, to the first thousand nurses who had joined the National Pension Fund for Nurses. A large proportion of the thousand nurses did actually attend on the occasion in question. Established only three years ago, it must be admitted that the success which the Fund has already attained is phenomenal. It owes its origin to the generosity of four city merchants—one of them (the late Mr. Junius S. Morgan) an American citizen—who gave a sum of £5,000 each, thus enabling £20,000 to be

deposited with the Court of Chancery, so that the fund could be incorporated under the Insurance Companies Acts. Mr. J. S. Morgan subsequently gave a second donation of £5,000. The invested funds now amount to £67,000 (more than one third of a million dollars), and of this sum nearly forty thousand pounds has been received in voluntary donations—the balance representing the contributions from nurses to the Fund.

Two noteworthy deaths have just occurred—those of Sir Edwin Chadwick, and Professor William Kitchen Parker, respectively. The former was not a medical man and was, in fact, originally educated for the legal profession. Sanitation, however, early attracted his attention, and during the last sixty years he has been one of the foremost exponents of sanitary reform. He died this day week, at the patriarchal age of ninety.

Professor Parker was a medical man, but it will be as a zoologist—not as a practitioner—that he will be remembered. His medical qualification was for years only the license of the Apothecaries' Society, and it was only in 1873, after attaining distinction, that he became a member of the College of Surgeons.

The Council election at the College of Surgeons comes as a disappointment to those who are ardent advocates of reform at that institution. Of the three candidates elected only one, Mr. Mitchell Banks, is in favor of reform, but the would-be reformers may derive some consolation from the fact that Mr. Banks heads the poll by a considerable majority over the next two candidates elected. Mr. Bryant has been elected to the Presidency of the College in succession to Mr. Jonathan Hutchinson.

DOWN IN DIXIE.

A Second Birmingham, Ala., Letter.

(From our Special Correspondent.)

To the Editor of the Medical Record.

Sir: The letter which I recently sent you from Birmingham, and which appeared in your issue of July 5, 1890, has met with such a flattering reception, that I am tempted to write you a quasi-continuation of my observations in the New South. It is an indisputable advantage of mental photography that the supply of sensitive film-plates need not become exhausted, until the first serious symptoms of cerebrasthenia are noticed by the supplier. Even a large-sized Kodak holds but a limited amount of impressionable material. But a well-regulated Northern encephalon, on its virgin trip through the South, is almost all impressionable stuff. You just drop a nickel in the cerebral slot, as it were, and take out a brand new impression on anything that may have happened within the limitless horizon of the mind.

The Colored Problem Again.—It is, of course, not to be expected that these nickel-in-the slot views can please everybody. Human nature is not made that way. It would kill variety, the very essence of life. But you step on my corns and I'll step on yours, has always been considered good Christian doctrine. I have been taken to task for solving the race problem, which is a question that was never intended to be solved at all. So say my critics, and critics always know. I am one of them myself.

Now, it must be painfully humiliating for the light comedian to have his audience provoked to tears of sad emotion, when his sole purpose was to make them lacrymate with laughter. Yet such a fate will have to be my sorry portion, if the *Birmingham Youth-Herald* and its journalistic me-too, the *New York Tribune*, are to be credited with the possible expression of unbiassed conviction. At any rate, these leading Administration sheets solemnly agree on the one vital point of violently denouncing my impertinent solution of the race problem. But they might as well stop fulminating. The problem *is* solved, and will remain so. The negro question is no longer a live political issue. The Force bill comes too late now. I cannot tell a lie, I did it with my little yel low dog.

For those interested in history I may say that Judge Fenner, of the Supreme Court of Louisiana, has just published a lengthy article on this self-same problem, in the June number of *Belford's Magazine*. Had this learned legal luminary known how speedily the question was to be finally disposed of, he probably would never have written the following: "The negro must, therefore, understand that the race problem is not a Federal question; that it is a false and foreign issue in national politics; that the Federal Government lacks the inherent power to deal with it; that its interference provokes and creates evils which it is powerless to remedy; and that, if the problem is to be peacefully solved at all, it can only be by the action and co-operation of the people, white and black, of the several States.

"Turning to these inevitable and exclusive factors in the solution of this mighty problem, we feel ourselves lifted into a different sphere of motive, of action, of responsibility. The meddlesome impertinence, the rash empiricism, the irresponsible tinkering, the petty and sordid considerations of party advantage, the arch insincerity which, at bottom, desires nothing so little as a peaceful solution and hails every outrage as fresh grist to the political mill, and all the kindred follies and frivolities which characterize the treatment of this question as an issue of national politics, pass into the limbo of utter insignificance and irrelevancy.

"To the whites and blacks of the South this question presents a different aspect. It looms before them as a gathering thunder-cloud, black with wrath and desolation, instinct with lightnings, whose fugitive bolts already strike, now here, now there, solemn warnings of the consuming fires which, if that cloud bursts, will scorch and wither this fair land.

"It behooves us, brethren, white and black, to take counsel together, while there is yet time, to see what we can do to avert this peril and to solve this problem which God has given into our hands. Whither are we drifting? Toward a war of races. Not, perhaps, a war fought in the open field, with organized battalions; the forces are too unequal for that; but toward a settled and perpetual race-conflict, inspired by mutual hatred, suspicion, and distrust, with opposing forces mustered in every village and hamlet and household."

In conclusion the author of this powerful essay says that: "If the negro seeks a higher and a nobler destiny, Providence points it out to him with unerring finger. An undeveloped continent, the birthplace of his race, lies before him, peopled by millions of his brethren, who exist in the same state of ignorance and barbarism from which slavery extricated him. If he is capable of standing alone, of maintaining and of spreading the civilization which he has acquired, there is his true field, to which he is called by every sentiment of duty to his race and to its birthplace. I talk not of deportation, or of any sudden or rapid exodus stimulated by artificial aid or exhortation; but of a natural, gradual, voluntary movement, under the influence of high motive and of wise consideration, which will accomplish itself gradually, safely, and without shock, according to the laws which govern the shifting of population."

Now, with all due deference to Judge Fenner, I submit that his advice comes about as near to my yellow-pup solution as a black cat does to a white one, on a dark night. I almost feel convicted of plagiarism in having unwittingly put his legally-clad suggestion into plain English. But this is a medical journal and, therefore, let us play ball.

Southern Fever versus Typhoid Fever.—Fever is very prevalent in the South. There is much difference of opinion among medical men as to the true nature of the continued febrile affections that have their home there. After much study of this moot-question, after earnest

conversation with leading Southern practitioners, and after some slight personal experience, I have come to the conclusion that Southern fever, or fevers, ought to be restudied and rewritten, in the light of modern research. What we want to know is the pathology of these conditions. What, if any, are the specific microbes belonging to them? Is the malarial organism pathognomonic of paludal poisoning? Does it occur only in true malaria? Is there a mixed infection from typhoid bacilli and malarial micro-organisms? These and kindred questions have suggested themselves to me, as they probably have to others. Why do not the Southern physicians bestir themselves to give reliable answers to them. We have had enough of mere clinical observation. We have had enough loose and hap-hazard society talk, representing the views of Dr. So-and-so, and the totally divergent views of his fellow-practitioner, Dr. This-and-that, from the same town. What good does it do for one man to get up and solemnly declare that all these cases are instances of typhoid fever, when an equally honest and accurate observer will rise immediately afterward and stake his reputation on the positive assertion, that they are without exception continued malarial fevers. Even in America we have happily outlived the era in medicine when the slightest value attaches to views so loosely expressed. We need accurate, scientific research, coupled with experimental and clinical observation, that will stand the test of ready confirmation by independent investigators. Anything short of this will be rightly considered mere verbiage or padding.

It is for this reason that I refrain from putting side by side, as was my original intention, two tables comprising groups of symptoms that were to serve as a means of differential diagnosis in cases of Southern fever. The one group contained the symptoms of typical typhoid fever, as ordinarily seen in the North, and the second, supplied by two busy practitioners of Birmingham, contained the symptoms alleged to belong to "Birmingham fever."

A Word of Warning Concerning Birmingham.—That the Southern fever of the city mentioned is more apt to be an atypical typhoid than a paludal fever, I am convinced of, for the simple reason that a severe epidemic of true typhoid fever occurred there in 1881. At that time the place had a population of perhaps four thousand, and five hundred cases (at a low estimate) of typhoid fever were observed. (See *Transactions of the State Society of Alabama*, 1881.)

In every succeeding year since then, many "fever cases" have occurred. And there can be no doubt that endemic influences exist in Birmingham to perpetuate the fever. That malaria is also rife there, and may complicate a given case, does not in the least militate against the view that most of the "Birmingham fever" cases are really instances of true typhoid fever.

So long, therefore, as the sanitary conditions of Birmingham remain in their present state, it is an excellent place to stay away from. But if a Northerner must needs go there, let him not be unmindful of certain necessary precautions as to drinking-water, food, clothing, etc. I would also warn any Northerner about first going there in the summer months, the fall and winter months being less dangerous.

Conscientious practitioners there will agree with me, in strongly urging the immediate transportation to a climate or place free from "local influences," of any fever case that is at all suspicious, especially when it happens to affect the person of one not yet thoroughly acclimated.

A Visit to the Pratt Mines.—About seven miles out from Birmingham, by the Ensley City Dummy, you reach the largest coal mines in the South, the famous Pratt mines. The daily output from these mines is nearly five thousand tons, and many hundreds of laborers find steady employment there. Coal is mined in six slopes and two shafts. Shaft No. 1 and slope No. 2 are peculiar in being worked under the reprehensible system of convict labor, which still obtains in the State of Alabama. Most of the convicts are colored, and the offences for which they do hard labor are often of the petit larceny kind.

The unaccounted-for acquisition of property in the chicken and watermelon line, usually entitles the discoveree to mine coal for the Pratt people, for a very arbitrary period of time. The State treasury benefits thereby to the extent of about thirty-five cents per day, the sum paid by the mine owners for every working convict. It is a beneficent system, which makes coal cheaper than it would otherwise be. But the colored people hate the very name of "Pratt Mines," which is to them the American synonym for Botany Bay.

The village of Pratt Mines is a straggling conglomeration of white cottages and black squatter huts. Doctors are plentiful even there. A constantly shifting population of about seven thousand is supposed to support twelve doctors. An intelligent-looking variety-store-keeper, when questioned how so many doctors managed to get a living out of so few people, said: "Well, Cap'n, I dunno haow thay do it, but thay do do it for a fack," which answer was probably strictly true.

The Prison Hospital of Pratt Mines.—This little hospital appeared to me a model institution of its kind. A neater, cleaner, more inviting infirmary I have rarely seen. The credit for this spick and span, new look of the hospital is due entirely to the vigilant care of the doctor in charge, who is himself a convict. It seems that this physician, who received me with the grave dignity and stately presence of an old-time courtier, once held a public office of trust. In a moment of alcoholic relaxation a petty embezzlement became his guilty misfortune. Five years penal servitude seems harsh punishment for a slight offence. But justice is too often a farce down in Dixie, at least for white crimes. Perhaps such lessons will produce salutary effects. It seemed a pity, though, that a gentleman of such evident culture, a physician of unusual learning, a man whom nature seemed to have intended for high stations, should spend his days in ministering to the wants of ailing negro convicts.

Birmingham's Chief Industries.—The Magic City is completely encircled by a mighty belt of furnaces, coke ovens, iron and steel plants, rolling mills, and factories of all conceivable kinds. Hundreds of tall chimneys "belch fire and rolling smoke" all night, long as well as in the day-time. The furnaces are compelled to do business twenty-four hours a day, seven days in the week, just like the leading saloons. Most of the latter (and there is quite a sprinkling of latters) are "open all day," their pan-nocturnal patency being a matter of course. As for the spirits conducive to healthful life and multifarious activity, commend me to a Birmingham night following pay-day. It is the Saturday pay that makes a quiet Sabbath, though it fills more bed-rooms with big heads than church-pews with wide-asleep conformers. But towering far away and above the inland industries already mentioned, there rise before the awe-struck gaze two grasping monopolies. They are the totally-eclipsing chewing-gum trust and the consolidated patent medicine syndicate. It is true, some able-bodied men do find employment in iron foundries, in factories, shops, and warehouses. But everybody, man, woman, child, and mother-in-law, is permanently engaged in the chewing-gum field of labor. Cotton was king in the South, years ago; but he has abdicated, and the royal prerogatives have fallen on the graceful shoulders of Queen Gum. So it happens that any leisure moments that the loyal subjects of her Majesty of Spruce and Tolu are able to snatch from those arduous duties which may be called the stress of chew, are devoted to the hopeless consumption of patent medicine.

One of the most eminent Southern statisticians, a man who has devoted his entire life to the elucidation of the gum question, informs me that the last census contains a gross libel upon the fair fame of the sunny South, in placing the per capita daily mastication of gum as low as seventeen packages. He asserts that the corrupt per-

son who compiled these figures must have been entirely out of his census, and should chews another calling. In 1890, he feels assured, the honest enumerator will vindicate the chewing capacity of the indigenous citizen by a truthful statement of the real facts. Nobody down here, with an iota of respect for himself or his surroundings, no person of chivalrous disposition, of dignity, patriotism, or positive religious convictions, was ever known to chew less than twenty-nine different varieties of gum, every waking day of his, her, or its life. In fact, I distinctly recall a professional sleeping beauty, who diligently masticated while Morpheus hugged her in close embrace. But Southern gum is good gum, that is true, and while testing its various virtues, I often felt impelled to wish for a speedy metempsychosis into the higher order of ruminantia. So, too, the propriety of lending proper emphasis to a plain statement, by invoking "gum," no longer admits of any doubt in my mind.

As for patent medicines, they or their initials thrive on every fence, grow on all trees, luxuriate in undisputed possession of every nook and cranny which is not already filled out by a healthy real estate boom. If you want to study the astounding capability of combining in countless ways the innocent letters of our meagre alphabet, go to Birmingham, and study its surroundings.

The Beauties of Nature.—The S. S. S., the R. R. R., the W. W. C. (I can assure suspecting readers on good authority that the first W. does not stand for women's) the X. X. X.—these and untold other letters, presumably pregnant with deep significance, adorn the landscape in such fashion that poor nature is put to shame, and accordingly keeps her head hidden from sight. Thus no flower blossoms in Birmingham, no luscious vegetable puts forth tender buds of hope, the woodbine twineth not, neither does the cranberry cran. A sterile plain, heavy-laden with stifling dust; zephyrs on whose wings are wafted breezes that smut your face and cover you with a dismal film a mummy would take pride in; no songbirds to gossip in the sulphur-charged atmosphere; no tempting river suggestive of a coolness that the furnace-heated air can never hold—such are some of the natural advantages possessed by this subtropical town. Man has added to these blessings the ceaseless din of dummies, the rush and roar of trains, the steady screech of steam-whistles, the harsh clang of bells, the rattling of heavy carts over hard pavements—this to please his ear. The structures he has reared to favorably impress the sight, the smells he has established to pleasantly titillate his olfactories, the menus he has concocted to agreeably touch his palate—all these things, although pertaining chiefly to the grosser senses, he has already brought to a rare degree of perfection. And the future is still before this Birmingham. But mortal pen must pause on the threshold of the possible. What lies beyond is all "imagining," and bereft of the good sense that the reader has the right to demand of your correspondent.

CATS, CHICKENS, AND DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: In your issue of June 21st, you commented upon Dr. E. Klein's investigation of diphtheria as coming directly from the cow and cat.

I would like to narrate three cases of diphtheria that occurred in one family, in my practice about three years ago. On May 6, 1887, I was called to see a little girl two years of age who was taken with malignant diphtheria. She lived five days and died a horrible death. Isolation, disinfectants, and all other precautions were used to prevent the remaining three children from taking the dreaded disease, but, notwithstanding all this, only a few days elapsed before it had marked a boy of eight years for its victim, and in five days he died. Not long after this the third child, four years of age, was taken with the same disease, and he lived two weeks and died with paralysis. Different physicians were called in consultation in these cases, but all our efforts would not check the onward march of the disease. As it manifested itself in such a malignant form the father and myself thought we would search the cellar and yards for the cause. Nothing was found that aroused our suspicions excepting some damp and decayed boards in the cellar and a dead cat under the piazza.

A few days after this the father read and showed me an article in the *New York Times*, in reference to the fatality of diphtheria when contracted from the lower animals. He then narrated to me the following story:

"Previous to my children's sickness they had a pet cat of which they were very fond. It was taken sick very much as my children were with swollen throat and running at the nose, and as it wandered away we saw it no more. Thinking it was dead I immediately got another cat for the children, and that was taken with the same symptoms and soon died. Also some chickens in the back yard were found dead."

After hearing this story I was not long in deciding the origination of the disease as far as the children were concerned, as the first child was taken only a few days after the death of the cats and chickens.

RED BANK, N. J., July 17, 1890.

INFANT FEEDING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: At this season every year the subject of infant feeding comes up as vigorously as if it had not been exhausted long ago by the annual onslaughts of hundreds of physicians in city and country throughout the world, and at this late day it would demonstrate a condition of highly developed egotism for a person to presume that anything entirely new could be suggested. But as we profit often by comparatively unimportant observations, my plan of feeding these slight specimens of humanity may be admissible.

There is nothing among the many prepared foods, in my opinion, as good as cow's milk, but very much depends on the quality. In small villages, such as ours, or in country districts, milk is obtained from adjacent farms, where, during the summer months, the cows are allowed to graze. This is not objectionable provided the pasture lot is free from noxious weeds, but the rule is that weeds are abundant, and of course the cows have free access to them. My experience and observation prove that the action of the infant's bowels is a pretty accurate indicator in this matter. As soon as the cows begin to feed on this unwholesome provender diarrhœa will begin its depleting ravages. It has been my practice for the last five years—whenever practicable—to see to it that the cow or cows are healthy and in good condition, feed them good clean hay and grain, which will produce good pure milk. In the bottom of the pan into which the milk is strained a small hole should be cut and a cork inserted. After waiting a short time for the cream to rise to the surface, the cork is removed and nearly or quite one-half the contents allowed to run away, when the cork is again inserted. The remaining milk will be rich in fats and proportionately free from caseine. This, properly sweetened and diluted, furnishes, I believe, a food for infants second in value to nothing, save good wholesome mother's milk, which is, at the present day, exceedingly difficult to obtain.

Small-pox	0	0
Varicella	4	0
Pertussis	4	15

Prince Bismarck and the Young Physician.—There is an old story which has lately been revised and is now going the rounds of the press, both lay and medical, which is not improbable in its conception, and which is worth repeating for the benefit of some of the younger generation who may never have come across it. It is stated that Bismarck once called in a young physician who had been very strongly recommended to him. The doctor naturally questioned his illustrious patient very closely as to the nature of his symptoms, their duration, degree of severity, etc. The Prince is nothing if not grouty, and not relishing this cross-examination, dismissed the physician with scant courtesy. The latter hastened to depart, but before making his final adieu, offered the suggestion that the best thing for the Prince to do would be to send for a veterinary surgeon, since the latter never put any bothersome questions to his patients.

To Dry up the Secretion of Milk.—Dr. Darey reports in the *Montreal Medical Journal* a case of supernumerary breasts, in which it was desired to dry up the secretion of milk in the extra mammæ. This the patient assured him that she was always able to do by making a hot saturated solution of common salt, and applying it constantly on cloths as a fomentation.

Insanity in Italy.—It is stated that insanity is constantly on the increase in Italy. The proportion of lunatics to the entire population is nearly as one to one thousand, whereas seven years ago it was as one to one thousand four hundred and seventy-six. Among criminals the proportion is very great, being in exact figures 12.25 per thousand.

Camphoric Acid in Night-sweats.—Dr. Fürbringer recommends, in the *Charité Annalen* for 1890, the use of camphoric acid in an evening dose of thirty grains in capsules against the night-sweats of phthisis. It may be given also in alcoholic solution, if so preferred. A trial of a solution of the same remedy applied locally did not give satisfactory results.

Codeine as a Narcotic.—As a remedy to quiet abdominal pain, codeine has been recommended by Brunton, and in a short paper by Dr. G. Kolber, its use is advocated as a substitute for morphine in tubercular disease of the lungs and larynx. It has the advantage over the usual substitutes for morphine—such as the extract of hyoscyamus, extract of cannabis indica, and so on, in being more reliable in its action, and without some of their drawbacks. Systematic trials with codeine were made on more than seventy patients of various ages for a considerable period. The dose was from one-half to two-thirds of a grain, or from a grain and two-thirds to two and a half grains daily. It is, however, better to give large single doses than small and more frequent ones; for example, half a grain morning and evening is more effectual than a grain and a half in small divided doses throughout the da In some debilitated patients doses of half a grain caused vertigo and mental dulness; when the dose was reduced these symptoms disappeared. With very weak subjects it is well to begin with smaller doses than half a grain. It also has the advantage over morphine of being less constipating, though there are cases, as tubercular disease of the intestines, where it is desirable to check the diarrhœa with opium. When used in bronchial catarrh the patients expectorated more easily and less frequently. In simple chronic laryngitis morphine was found to be more reliable than codeine. In spite of the many desirable qualities possessed by codeine, it is, of course, less reliable in its action than morphine, but in many cases will answer as an excellent substitute for the stronger alkaloid.—*The American Journal of the Medical Sciences*, July, 1890.

Congenital Defect of the Pectoral Muscles.—Dr Benario reports a case of congenital absence of the pectoral muscles on one side of the chest which was observed in Professor Brieger's clinic. The subject of the deformity was a man aged twenty. On the right half of his chest in front the skin lay close upon the ribs, the pectoral muscle being altogether absent. Between the chest and arm there was felt beneath the skin a peculiar membranous extension, called by the author "flughautbildung;" also "schwimmhautbildung." There was slight right convex scoliosis. The right upper limb was shorter than its fellow (4 ctm.). Electrical examination proved that the condition was congenital, and not due to juvenile atrophy. Thirty cases of a similar nature were found recorded in the literature, 24 with absence of the pectoralis major, 6 with absence of the pectoralis minor and major together.—*Medical Recorder.*

Relics of Barbarism in the German Universities.—With all their learning and teaching power, the German universities retain some rather unlovely traditions, of which duelling is perhaps the most redolent of barbarism. True, the vast majority of "hostile meetings" between undergraduates seldom result in more than facial disfigurement; but sometimes, when firearms are the weapons chosen instead of swords, danger is inevitable, and even death may occur. A melancholy illustration of this has lately been witnessed at Wurzburg, where a highly promising and amiable "candidatus medicus" lost his life. Paul Fleurer, the unfortunate youth in question, seems to have played a truly chivalrous part in the encounter; for after a first, and then a second, interchange of shots, he held out his hand twice in token of reconciliation with his antagonist, but in vain. A third interchange was insisted on, and poor Fleurer fell mortally wounded, and died in a few minutes. At his funeral, which was attended by the students in large numbers, and with all the insignia of mourning, *oraisons funèbres* were delivered, the principal of which referred to the deceased as the victim of an "unfortunately still prevailing prejudice"—surely an inadequate condemnation of a practice which finds no favor in the better-mannered academic life of Great Britain and America.—*The Lancet.*

ARTIFICIAL PROLAPSE OF THE UTERUS—ITS DANGERS.[1]

BY H. C. COE, M.D.,

NEW YORK.

THE term "artificial prolapse" is of foreign origin, and is usually understood to signify downward traction upon the cervix sufficient to bring it to, or through, the vulva in order to facilitate diagnostic or operative manipulations. This procedure is generally recommended in English, French, and German works on gynecology, which usually devote a separate chapter to the subject. We are all familiar with the classical figure in Savage's monograph, illustrating the ease with which the uterus may be dislocated downward, and change in the anatomical relations of the pelvic organs which results from this extreme downward traction. It should be remembered, however, that this "displacement of the pelvic floor segments," as Hart and Barbour term it, is such as occur under perfectly normal conditions, and cannot be regarded as representing what actually takes place in ordinary practice. The reader of the foreign works to which reference has been made, would naturally infer that artificial prolapse was a simple and harmless procedure, similar to the passage of the sound. It is true that certain contra-indications are always mentioned, but only in a cursory way, and not in such a manner as to impress upon the tyro the fact that there are risks attending this procedure which should make him somewhat cautious about resorting to it except under certain clearly-marked conditions. We are inclined to be more conservative in this country, as will be evident by comparing the chapter on this subject in Hart and Barbour with the corresponding section in Mundé's "Minor Surgical Gynecology." It is the writer's purpose to briefly emphasize the cautions laid down by the latter writer, with the addition of some comments based upon the results of personal experience and observation. It may be assumed that nothing will be presented which is new in theory (if not in practice) to the specialist. The subject naturally divides itself into two heads—artificial prolapse of the uterus as practised for diagnostic purposes, and that for operative purposes. The conditions in the two are evidently somewhat different, since in the former case the patient may or may not be anæsthetized; in the latter she is under the influence of an anæsthetic.

I. **Downward Displacement of the Uterus in Order to Facilitate Diagnosis.**—In Hart and Barbour's manual the volsella is regarded as the proper instrument to be used for this purpose, and a separate chapter is devoted to it. The most recent work on operative gynecology (by Vulliet and Lutaud) also recommends its use. Professor Alexander Simpson early set forth its advantages in his "Contributions to Obstetrics and Gynecology." It is hardly necessary to describe the manipulation. The anterior lip of the cervix is grasped with the volsella and the uterus is drawn downward, while the examiner introduces his finger into either the rectum or the vagina—in the former case with the view of mapping out the fundus uteri, the adnexa, and morbid growths within the pelvis, in the latter usually, for the purpose of exploring the uterine cavity, after previous dilatation of the cervical canal. We may dismiss vesical exploration as a method of examination that has happily become obsolete. Examination per rectum with the uterus thus dislocated is commended as a means of diagnosticating displacements of the uterus and adnexa, and determining the relation of intrapelvic and abdominal tumors to the uterus. When it is necessary to introduce the finger into the uterine cavity for the purpose of detecting morbid growths, this manœuvre is undoubtedly facilitated by drawing the organ downward, with or without simultaneous pressure upon the fundus from above.

With regard to this aid to diagnosis it may be said that it is employed much less frequently than formerly. Davenport, in his excellent little work on non-surgical gynecology, makes no allusion to it. It is certain that since we have had such frequent opportunities of comparing the diagnosis made at the examining-table with that established after opening the abdomen we have advanced considerably in the refinements of pelvic diagnosis. It is true that there is danger that we may go to the other extreme and venture upon radical operations after such a superficial examination as that described in Tait's recent work, but the conscientious gynecologist who is constantly seeking to profit by his mistakes in diagnosis is bound to learn a useful lesson in this direction from every case of laparotomy. Now, experience in the operating-room and in the dead-house has shown that it is precisely these doubtful tumors, in which downward traction upon the uterus is recommended for the purpose of more clearly defining their relations, which cannot be displaced without danger. Of course all authors mention as contra-indications to artificial prolapse acute and subacute perimetritis and recognized disease of the tubes, though it is noticeable that Vulliet and Lutaud make no reference to the latter complication. It may be granted, then, that since most of these books were written we have learned a great deal more about the danger of interfering with adherent tubes and ovaries, unless we intend to remove them. The French authors alluded to are certainly unsafe guides for the inexperienced, inasmuch as they not only state that many gynecologists have been deterred from resorting to artificial prolapse through fear of "causing imaginary troubles," but strongly recommend it as the best means of determining the existence of pyosalpinx and chronic oöphoritis. To the mind of the reader this is dangerous teaching. If we have not yet learned to recognize disease of the adnexa by the ordinary methods of examination we have profited little by the vast amount of experience accumulated during the last five years. We are told that the relations of abdominal tumors to the uterus can be best ascertained by drawing the latter organ downward. That this procedure is not free from danger will be apparent to anyone who has observed a number of laparotomies for adherent ovarian cysts. We have made advances in the differential diagnosis of abdominal tumors, also our friends, the electro-therapeutists, have taught us to differentiate more exactly the various forms of fibromata, so that we hear less often of cases in which these are mistaken for ovarian cysts. Personally, the writer believes that the intelligent practice of the bimanual (with either vaginal or rectal examination) ought in the majority of cases to tell us whether a tumor is of uterine origin or is merely adherent to the organ. Cases should be rare in which it is necessary to dislocate the uterus by downward traction in order to settle this point.

[1] Read at a meeting of the Section on Obstetrics, New York Academy of Medicine, May 22, 1890.

The writer never remembers having seen artificial prolapse practised for this purpose during the seven years of his connection with the Woman's Hospital.

When we come to the second class of cases in which this manipulation is practised for diagnostic purposes—those in which it is necessary to make digital exploration of the uterine cavity—it is evident that the conditions are quite different. Here the trouble is supposed to be entirely intra-uterine, the uterus is freely movable, and the patient is preferably anæsthetized. Doubtless the uterus may be prolapsed under these circumstances with a minimum of danger and with great advantage to the examiner, it being assumed that he has previously made a thorough examination of the pelvis after the patient is under ether, in order to determine positively that no contra-indications exist. But even here the writer would limit its application to cases in which the uterus is situated so high up in the pelvis that it cannot be pressed down from above sufficiently to allow the finger to pass the os internum. The better way, unquestionably, after insuring proper dilatation with tents, is to insinuate the finger within the canal, and steadily and gently press the uterus down upon it, just as one would work on a tight glove. In this way the necessary amount of downward dislocation can be exactly regulated, and the counter pressure exercised from below prevents any sudden slipping of the uterus.

Much more might be added with regard to the estimation of the size of the uterus and the recognition of displacements by the aid of downward traction, but it must occur to every gynecologist that he who is obliged to resort to it for this purpose must have learned imperfectly the elementary principles of his art. In leaving this branch of the subject the writer would state his belief that, in view of the recent advances in pelvic diagnosis, artificial prolapse of the uterus should rarely be practised for the purpose of determining the relations of abdominal tumors, and never in cases of adherent intra-pelvic growths, whether tubal or ovarian.

II. **Downward Displacement of the Uterus in order to Render the Field of Operation more Accessible.**—It is important to distinguish at the outset actual traction upon the uterus with the volsella from mere steadying of the organ with the tenaculum. This is not made clear in any work to which I have had access. Yet the distinction is a vital one. There is a great difference between holding the uterus at, or near, its normal plane, and dragging the organ down to the vulva. This extreme traction not only renders the parts more accessible during the removal of intra-uterine growths, trachelorrhaphy, amputation of the cervix, or vaginal hysterectomy, but also sensibly diminishes the hemorrhage by diminishing the calibres of the tortuous uterine blood-vessels, as was long pointed out by Dr. Emmet. The question is whether these advantages counterbalance the dangers. These dangers may be stated briefly as follows :

1. Overstretching of the already relaxed supports of a heavy uterus by prolonged traction, so that they do not recover their former tone. This is not entirely theoretical.

2. Overstretching and tearing of peri-uterine adhesions, thus setting up fresh inflammation.

3. Injurious traction upon a pyosalpinx or abscess of the ovary, causing rupture of the same with escape of its contents into the peritoneal cavity ; or, setting up a fresh peri-oöphoritis or perisalpingitis, thereby greatly aggravating the existing trouble.

It may be objected that no careful surgeon would exert undue traction upon a uterus which is fixed by old adhesions, or when an adherent tube or ovary can be felt. But with the patient thoroughly anæsthetized, the parts become so relaxed that even a moderately adherent uterus may appear to be freely movable, while we are deprived of a most important danger-signal, the expression of pain by the patient. Cases are on record in which fatal peritonitis has followed traction upon a supposed mobile uterus.

Now, the writer does not make these statements unadvisedly, since during the past winter he has seen several well-marked cases of serious pelvic inflammation following excessive traction upon the uterus during operations upon the organ. For obvious reasons, cases of septic infection are excluded from this number, so far as it is possible to do so ; pure traumatism, not sepsis, seems to be the etiological factor.

It is practically impossible (outside of a private hospital) to keep a patient under preparatory treatment until every vestige of former inflammation has disappeared, before performing an operation upon the cervix. The fact is that all of us do, and must, operate sometimes when the uterus is not freely movable, or when perimetric indurations, ovaries, and even tubes, can be felt. The writer does not propose to discuss the advisability of repairing a lacerated cervix when the uterus is retroflexed and adherent ; personally he is opposed to it, not so much on account of the immediate dangers, but because the operation does little or no good, since the patient's condition is practically the same as before. The cervix "looks better," that is all.

To return to the subject of complications resulting from artificial prolapse. Within the last five months the writer has noted the following cases of periuterine inflammation, apparently due directly to traction during operations :

Case I. *Laceration of the Cervix.*—Uterus fairly movable. Prolapsed right ovary (or tube?). Excessive traction during operation. Acute perimetric trouble on right side, so severe that patient's life was despaired of. Pelvic abscess developed and was incised. Protracted convalescence with permanent induration at the site of the abscess.

Case II. *Retroflexion with Partial Fixation ; Stenosis of the Cervical Canal.*—Divulsion and stem inserted. No febrile reaction, but patient had pain in right side on recovery from ether and developed a small pelvic abscess to the right of the uterus, which is gradually becoming absorbed.

Case III. *Laceration of the Cervix and Perineum.*—Uterus prolapsed, but retroflexed and somewhat adherent. Under ether the uterus was so freely movable that the cervix was drawn down to the vulva and the laceration repaired with unusual ease, perineorrhaphy being performed at the same sitting. Patient developed a low form of perimetritis, which considerably prolonged her convalescence and left her worse than before the operations, both of which were fairly successful from a cosmetic stand-point.

Case IV. *Epithelioma of the Cervix.*—Enlarged and adherent ovary behind the uterus. High amputation under rigid antiseptics, according to Baker's method, during which the uterus was drawn forcibly downward with a volsella. Acute oöphoritis and peri-oöphoritis, which, though localized, gave rise to alarming symptoms and retarded convalescence. Perfect recovery, but uterus less movable than before, and ovary remains quite tender.

Case V. *Epithelioma of the Cervix.*—Prolapsed left ovary, with history of left-sided parametritis a few years before. High amputation was done, the uterus being drawn downward as far as possible. On account of hemorrhage from the uterine arteries it was necessary to extirpate the entire organ, which was done without difficulty. Tubes and ovaries adherent and not removed. Parametritis on left side appeared during the first week and the patient narrowly escaped with her life and an induration which extended parallel with Poupart's ligament, and did not disappear for a couple of months. Sepsis carefully excluded. The patient (who is now quite well) said that this attack was exactly similar to the former one.

Examples could be multiplied, but the above are sufficient to illustrate the complications which may arise from strong downward traction upon the uterus, when the organ or its adnexa are adherent. The writer has seen masses appear within the pelvis so soon after operation that the inference was that they were hæmatoceles or hæmatomata due to the rupture of vessels in the broad ligament, whether from the rupture of adhesions or not could of

course not be determined. Now, is this excessive traction upon the uterus—and this is what we mean by artificial prolapse—necessary? Rarely. It is the best test of a skilful operator that he does not find this aid necessary. Of course in high amputation and total extirpation it is necessary to make more or less traction with a powerful instrument in order to render the parts more accessible, but it is not necessary to drag the cervix down to or through the vulva (as a German writer advises), with total disregard of the presence of perimetric adhesions. In cases of trachelorrhaphy artificial prolapse should be practically unheard of. It is sufficient to merely steady, not to drag down the cervix. This is the caution which the writer invariably gives to any assistant, no matter how movable the uterus may be; he not only teaches, but he practises it. To maintain the uterus in its normal position is sufficient; the operator should not seek to supply his lack of skill or unfamiliarity with gynecological operations by dragging the organ down to the vulva at the risk of setting up inflammatory trouble. Fixation, not traction, is what we should aim at. The ordinary tenaculum is not, in the writer's opinion, the best instrument to employ for this purpose, since it frequently tears out, lacerating the mucous membrane and requiring to be frequently readjusted; the double tenaculum, devised by Dr. Hanks, is admirably adapted for steadying the uterus without changing its position during the entire operation, while it is not sufficiently strong to tempt the surgeon to employ it as a volsella.

Before leaving the subject the writer would call attention to the result of excessive traction during trachelorrhaphy which he has frequently observed at the operating table. By drawing a short cervix forcibly downward it is apparently elongated so that an inexperienced operator might run considerable risk of cutting through the lateral fornix and opening up the subperitoneal space. A pelvic abscess might readily follow this mischance. The writer had such an experience in his first trachelorrhaphy. This mistake is common with the beginner, as he has frequently had occasion to observe in teaching operative gynecology.

In conclusion the writer would again emphasize the importance of distinguishing between fixation and downward traction upon the uterus, the dangers of the latter, and the fact that the advantages of artificial prolapse do not, on the whole, compensate for the risks incurred. As an aid to diagnosis it should be allowed to fall into "innocuous desuetude," and in operations it should be practised as a measure of necessity, rather than of convenience. As Mundé says: "It is evident that this method should never be employed needlessly, and only when the examination or operation cannot be as well performed with the uterus *in situ*."

THE CAUSES AND THE REMEDIES FOR SUITS FOR MALPRACTICE.[1]

By F. J. GRONER, B.S., M.D.,

BIG RAPIDS, MICH.

When this Society was divided into sections to facilitate scientific work, the new constitution provided that each section elect a member "whose duty it shall be to deliver an address before the Society in general session upon some subject pertaining to the department by which he is chosen." My predecessors have given such a complete account of the recent advances in surgery that I deem it not proper to traverse the same ground. The first address, "Surgery as an Art and a Science," was delivered by Dr. George E. Frothingham. Dr. Herman Kiefer delivered the second, "Surgery within the Last Fifty Years." These addresses are so able, so thorough, and cover the ground so completely that I feel compelled to seek another theme.

I shall depart from the almost routine precedent of every surgeon who has an address to deliver, and every president's address from a county society to an International Medical Congress, of heaping one round of eulogium on the surgeon. I wish simply to call your attention to something that is already known—not to something new.

I have gathered my information from various sources, and have tried to give proper credit. It is a subject in which all practitioners are interested, and surgeons in particular. The subject was very forcibly brought to my mind after spending my best skill on a young man who received a severe injury from a falling tree. The patient recovered, but one arm was paralyzed. A few months after the accident the patient and a guardian stepped into my office and said, "The arm was not set right, and you have to pay." Probably you can anticipate my feeling when I say I was young then.

Aside from the "beauties of the profession," the learning, the skill, the self-sacrifice, and even life itself freely poured out for unfortunate and injured humanity, you not only very often reap ingratitude, but you are confronted with suits for malpractice. Storms and even cyclones are necessary to progress. They purify the atmosphere and encourage wholesome growth; but we are inclined to believe that the criticisms and cursings are sufficient without the annoyance and expense of a suit at law.

It is said "there is no country in the world in which physicians and surgeons are embarrassed with suits for malpractice except England and the United States." The Western States enjoy an unenviable reputation in this respect. The medical profession is held to a stricter accountability before the law than any other class. Suits against corporations, lumber companies, railroad companies, and against physicians are pursued to an alarming extent. They appear to be especially epidemic in Michigan and some of the bordering States. The question for us is, What is the cause, and what is the remedy? Can we suggest proper treatment? The cause is undoubtedly greed for a fat remuneration. They are instigated by avarice, or they are undertaken to gratify some feeling of personal enmity. The ablest men of the profession have been obliged to defend themselves in these suits. There is scarcely a surgeon of any great experience in this State who has not either been prosecuted or many times threatened. I know of cases of injured reputation, financial embarrassment, and even mental wreck from the harassings of malpractice suits. It has been stated that some eminent practitioners of skill and wealth have avoided surgery, leaving it to men who had less reputation and less money to lose.

Dr. Hamilton tells us of a surgeon in Vermont who was prosecuted many years, in a case in which the plaintiff claimed damages on the ground that his wife had been treated for a fracture, and confined to her bed for several months, when no fracture existed, nor did the case leave the courts until the doctor had lost his property in the protracted defence—not, indeed, until the death of the woman enabled the defendant to show the broken bone as proof that he had judged and practised correctly.

You will find a very large percentage of suits for malpractice are brought by that species now denominated "crank." Many are dogged on by some shystering lawyer who is to receive half of the profits. Sometimes reputable lawyers are induced to take such cases by being deceived in the information the plaintiff pretends he can produce. Very often there is some Judas in the form of a professional rival who has first suggested a suit for damage.

The medical profession is held to a stricter accountability before the law than any other class. The general laws defining responsibilities and regulating practice are the same in regard to every profession and art. Why are we to be held exceptionally accountable? Why are lawyers not prosecuted for giving bad advice, which leads to defeat and disaster for their clients? Why not prosecute clergymen for malpractice? Their notorious omissions of duty, their multiplicity of creeds and doctrines, their multiple expositions and interpretations of the Divine

[1] Read before the Michigan State Medical Society, and printed in this journal with the consent of the Society.

word, their jealousies, differences, and contradictions must send many souls to perdition. Almost all educated physicians are agreed upon the management of a surgical case. It is not so in law. The opposing counsel give conflicting opinions. One must be wrong. They are often wrong in points of law. But you do not hear of suits of malpractice for these errors of opinion and practice. It certainly cannot be said that the surgeons in this country are not as thoroughly educated and as well qualified to practise their profession as the lawyers are to practise theirs. You all have had threats of suits for alleged malpractice by dead beats, when you knew it was only their favorite mode of cancelling their obligations for medical and surgical attendance. You are familiar with the poet's lines:

> "God and the Doctor we alike adore,
> But only when in danger, not before;
> The danger o'er, both are alike requited—
> God is forgotten and the Doctor slighted."

The manner of getting up these prosecutions you are quite familiar with. Certain members of our profession, that are allowed in the profession by practical absence of law, denominated quacks, or inferior, mischief-making physicians, detested by the profession and by all honorable men, and unrecognized by those whom they seek to imitate; conscious of their own inferiority, instead of trying to elevate themselves they attempt to drag others down. Jealous of those they cannot rival, they sow discord among their rivals' patrons, condemning the result of labor they dare not attempt to perform. Thus too often the seeds of dissatisfaction or distrust are sown among those who have been the subjects and recipients of surgical and medical treatment. How easy it is for such fiends, with their cunning ways and oily tongues, to make many patients believe that they have been subjected to some great wrong; that their broken and mangled limbs might have been in much better condition, their enfeebled health restored, had the skill and wisdom of the knaves themselves been put into operation at the proper time; when the plain facts are, their limbs have only been saved from being amputated by almost superhuman efforts, and by great skill the patients have been snatched from death's door. The pretenders will say, "Sue for malpractice." A new idea strikes the patient. Though the limb is much better than any reasonable man could have expected, yet it is not better than the uninjured one. Then to help matters along certain members of our profession have their counterpart in the legal profession, and a class of lawyers without respect or honor at home or abroad are anxious to engage in any meanness or rascality. They will prosecute for a percentage of the stolen booty; and if the evidence is not strong enough to convict they have a happy faculty of manufacturing to order such as is required. It is a just reproach that such persons are permitted to practise in the courts. The present age, with the exigencies of modern rascality, has brought into being the barnacles, vultures, and cormorants of both learned professions. I have no charge to bring against gentlemen of the legal profession. No one appreciates their great and good work more than myself. Their calling, like our own, demands the exercise of the highest faculties of man. I only allude to those who abuse their privileges.

Surgeons should be held strictly accountable for want of skill, or for negligence in the performance of their duties. We must remember that the principles of surgery cannot be fixed and permanent, they must advance with the progress of science. The science and practice of surgery has advanced to a degree of perfection beyond the most sanguine expectations of the past generation. There can be no fixed limit to the qualifications of the surgeon, for the required knowledge and skill rises in proportion to the value and delicacy of the operation. Every case necessarily has its own peculiarities, therefore, there can be no universal standard of treatment established.

The degree of care bestowed on each case must be such as surgeons of common prudence would employ. There is no standard of comparison by which to determine what is ordinary or reasonable care, but each individual case must stand upon its own merits (Hilliard). In the care of any case the surgeon must conform to established precedent, and be diligent in the application of remedial measures. Conformity to established rules of practice has from the earliest periods been rigidly exacted. It is held that any deviation from the established practice shall be deemed sufficient to charge the surgeon with malpractice, in case of an injury arising to the patient. This rule is designed to protect the community against reckless experiments, while it admits the adoption of new modes of treatment only when their benefits have been demonstrated, or where from the necessity of the case the surgeon must be left to the exercise of his own skill and experience (Stephen Smith). The possession of the requisite qualifications and failure to employ them sedulously for the benefit of the patient is negligence, and negligence is as much a fraud upon the employer as want of skill, for it is upon the diligent application of skill that the problem of success must rest (J. Ordronaux). It is held that whenever any important step in the treatment of disease is neglected, or any important stage of it overlooked, which might have been used for the benefit of the patient, then it may be averred that the surgeon has been guilty of negligence.

The law that covers pretty generally the points in a case of malpractice is found in Hilliard's "Law of Torts," second edition, vol i., p. 253.

I am not here to defend quackery. Men practise in this State without learning, culture, or character. Please remember that wherever there is an immoral or incompetent practitioner of medicine or surgery, he is there in defiance and in spite of the protests of the medical profession. It is the leading and wealthy men of the profession who are usually the targets for maligners. I read of one exception, however, a famous Dr. Walters, living in a neighboring State, a noted botanic or rutabaga doctor, told fortunes, etc. A wealthy lady was placed in his care by her husband for treatment, the doctor being so kind as to let her board in his family. After trying various remedies, all alike failing, he discovered she was bewitched. There was but one way, he gravely informed her, that the witches could be cast out; she submitted, but told her husband, who objected to the treatment and sued for damages, and the learned doctor was assessed $1,000, which he paid. But, as the story goes, that husband forever after discouraged the casting out of witches.

Of the many phases of superstition which have attained proportions that render them worthy of critical scrutiny, there is none so dangerous as that which makes its possessor the facile subject of conscienceless quacks and death dealing frauds. Few persons dream of the extent to which quackery is practised, or the hold it has upon many men and women who, one would imagine, were far above its influence. Only a few exceptionally atrocious cases are brought to the notice of the public, the obscurity of some of the sufferers, the reluctance of others to acknowledge that they ever have resorted to such irregular sources, serving as safeguards for the charlatans who torture them.

Where ignorance and conceit are the doctor's only outfit society should be afforded some effectual protection—something better than our present State law.

Physicians are no worse than any other men; the same principles of justice which regulate the responsibilities, liabilities, and duties of other individuals, should be applied to them. If he undertakes to perform the delicate duties which pertain to his profession without due preparation, and fails to bring into requisition available knowledge and skill, or if he wantonly injures, or neglects those entrusted to his care, he should be held accountable for the results. It would be a good deal better for all concerned if the ignorant, immoral, and unfaithful should be

restricted by law from engaging in practice. Ignorant men and women, and even some whose judgment on other matters is good, cannot discern between the quack and the physician. Let us have laws to aid them in their discrimination. There should be an end put to the unjustifiable lawsuits against skilful, attentive, and humane physicians. In order to protect the profession the persecuted member should not be allowed to suffer. The profession in any neighborhood cannot afford to allow a verdict to be taken against a defendant. It is very certain that they cannot convict without expert evidence, and they must call on the medical profession for that. The members of the medical profession should always stand by each other, then the benefit of the doubt can be given to the right side.

"Where a surgeon undertakes to treat a fractured limb, he has not only to apply the known facts and theoretical knowledge of his science, but he must contend with very many powerful and hidden influences; such as want of vital force, habit of life, hereditary diathesis, climate, the mental state, local circumstances, and a thousand other agencies. . . . These latent conditions often render the management of a surgical case difficult, doubtful, and dangerous; they are all potent causes, frequently having greater influence in the result than all the surgeon may be able to accomplish" (Elwell).

If the patient does not follow the prescriptions, and co-operate with the surgeon, he cannot afterward call the surgeon to an account for any unfortunate result that may attend the case.

In the case of McCandless *v.* McWha, the Supreme Court of Pennsylvania, said: "Nothing can be more clear than that it is the duty of the patient to co-operate with his professional advisers, and to conform to the necessary prescriptions; but if he will not, or under the pressure of circumstances he cannot, his neglect is his own wrong or misfortune, for which he has no right to hold his surgeon responsible. No man may take advantage of his own wrong, or charge his misfortune to the account of another."

The charges in the indictment are ignorance and unskilful treatment, or negligence. The law requires of a man who offers his services in any profession three things: That reasonable degree of learning, skill, and experience ordinarily possessed by others of his profession; reasonable and ordinary care in the treatment of the case committed to him; and the exercise of his best judgment in cases of doubt. A diploma is the best evidence of this degree of attainment; but, to be valid, it must be proved that the college from which it emanated had corporate authority to grant degrees in medicine at the date of giving the degree, and if the college of another State, its act of incorporation must be offered as proof of its authority to grant such a degree (Hunter *v.* Blount, 27 Georgia, 76; Hill *v.* Brodie, 2 Stewart and Porter, 56).

We may lay it down as a rule that the surgeon always does the best he can for the patient, be he rich or poor. No practitioner would be foolhardy enough to do otherwise. The charge of negligence is seldom sustained.

In the case of McCandless *v.* McWha, 22 Penn., 261, Woodward, J., says: "The implied contract of a physician or surgeon is not to cure, to restore a fractured limb to its natural perfectness, but to treat the case with diligence and skill. The fracture may be so complicated that no skill vouchsafed to man can restore original straightness and length, or the patient may, by wilful disregard of the surgeon's directions, impair the effect of the best conceived measures. He deals not with insensate matter, like the stone-mason or bricklayer, who choose their materials and adjust them according to mathematical lines, but he has a suffering human being to treat, a nervous system to tranquillize, and a will to regulate and control."

The doubts and uncertainties that constantly embarrass the surgeon are understood and appreciated by the intelligent, and the errors and mistakes to which they are thus unavoidably exposed may well furnish, in many important cases, a satisfactory explanation and excuse for any unfavorable results, which, upon their face, may appear to involve want of skill or knowledge.

In the case of Courtney *v.* Henderson it is shown that an error in judgment is not malpractice. "An error in judgment in a man skilled in a particular calling is not malpractice, unless it is a gross error. But an error in judgment in a science of a man unskilled in that science (if such a thing can be) is malpractice. In other words, a person attempting to practise in physic or surgery, without first having obtained a knowledge of such science, is liable for all the damage that is the result of his practice."

A large proportion of suits against surgeons arise from the treatment of fractures and dislocations. Frank Hamilton has ascribed the cause to the physician himself. He says: "We not only believed, but constantly taught, that we were able to make broken limbs more perfect than we actually could make them. We greatly underestimated the difficulties of diagnosis and of treatment in both fractures and dislocations. In my early days I was disposed to lay most of the blame upon lawyers. I supposed that a certain class of pettifogging lawyers hunted up these cases and incited the people to prosecutions. But I have changed my mind on this point. Perhaps they are in some degree responsible, but I am convinced that the responsibility rests mostly with ourselves. Many writers upon surgery and most practical surgeons have claimed too much. They declared that they could do many things which they could not, and their patients have simply taken them at their word, and required of them damages when they have fallen short of their own claims and promises."

One of the most valuable contributions ever made to American surgery is Dr. Frank Hamilton's series of papers on "Deformities after Fracture," published in the "Transactions of the American Medical Association" for the years 1866, 1867, 1868. We now know the usual amount of deformity in cases of fracture when treated skilfully. But every little while some surgeon comes out with a new method or new apparatus for treating fractures, and usually claims that his results are invariably perfect. We are still unable to make perfect femurs in all cases, or perfect clavicles. In fact, imperfection in all forms of fractures is still the rule, and perfection the exception. Holthouse says: "Surgeons are still to be found hardy enough or ignorant enough to repeat the fallacies which have been so oft refuted, and to vaunt their success in the cure of oblique fractures in the adult without shortening. Why do not these surgeons, instead of publishing their cases in the journals, produce their patients at some of the medical societies?" There must ever be differences of opinion in matters so difficult as the investigation of surgical cases. Conflicts of opinion on certain points are creditable to the independence of thought and the individual self-reliance that characterize professional opinion (Erichsen). However, it is not creditable to ascribe impossibilities to the surgeon, and some of our leading authorities attribute many of the prosecutions for malpractice to surgeons promising too much.

It is well to remember that in all suits for damages for bad results fraud on the part of the claimant is quite a common item in the legal investigation. The medico-legal aspect of a case depends on three things; careful prognosis, good witnesses, and careful records. Your prognosis will largely influence your patient's desire to bring the matter to trial. If the doctor is disappointed in his result, some one will suggest to the patient that he was incompetent or negligent. Too often the doctor has not given a correct prognosis, inasmuch as no one can promise a good result from any fracture. The physician may expect a good result and may so promise the patient, but if he is wise he will not do so. He should always let the patient know of the many possibilities of bad results from any fracture—erysipelas, inflammation, necrosis, non-union, anchylosis, shortening, etc. We are justified in showing up the worst before the patient, not with the

idea of winning great credit by a marvellous cure, but as a matter of self-protection. The prevention of suits for malpractice depends less on a surgeon's skill than on his ability to summon witnesses when it comes to trial. In treating a fracture, no matter how simple or how sure you are of a good result, have witnesses. You need an assistant in reducing a fracture. And if you are able to bring good witnesses, patrons and lawyers will be deterred from bringing suit against you. You should keep a perfect record of the case—details of examination, diagnosis, dates of occurrence and examination, names of witnesses, etc. All data should be preserved, for in case of suit they will be valuable.

The law does not require the highest degree of skill and science, but only such reasonable degree as will enable the person safely and discreetly to discharge the duties assumed. The failure of a course of treatment is not by any means conclusive of the want of professional skill by the practitioner; as such a rule would be harsh and unreasonable in application to any art or profession, and endanger the most faithful and the best informed.

We feel that a great and learned profession, whose charity knows no limit, should be protected from suits inspired by fraud, ignorance, and malingering. It has been suggested as a remedy that those physicians implicated are entitled to the sympathy and assistance of as many of their professional brethren as may be necessary to sustain them. And unless it is possible to avoid it, let not a member of the profession be found in the ranks of the prosecution. Professional sympathy, however, will not remedy the evil.

Elwell says: "The only effectual and permanent mode, it is believed, by which the evil can be reached, remedied, and guarded against, is by elevating the standard of medico-legal knowledge in the professions of law and medicine. It is not to be denied that members of the legal profession, with few exceptions, are imperfectly informed upon medical questions connected with law, though they may be well educated in law generally."

David Paul Brown said: "A doctor who knows nothing of law, and a lawyer who knows nothing of medicine, are deficient in essential requisites of their respective professions."

Prosecutions for malpractice occur so frequently that no surgeon, however respectable or eminent, has the assurance, in all his cases, that he will receive either gratitude or reward for his patience; indeed, the more he is informed upon the history and calamities of surgery, the more he fears for the results of his surgical practice.

One way to avoid the annoyance of these suits is to be honest with patients. Do not claim more than you can perform. If such suits do come they should not be compromised. It is unjust and only encourages others to institute them. The best legal talent and the best experts the country offers should be secured. If juries who cannot understand the many causes of failure of surgical cases find it easier to blame the doctor than the constitution of the patient; judges, whose duty it is to review the case, and whose function it is to sift evidence and to judge equitably, will probably remedy the evil by granting a new trial, which is equivalent to a verdict in the doctor's favor.

The most important measure for preventing such suits is to have a law compelling the plaintiff to give bonds to remunerate defendant a certain percentage of amount for which suit was brought, providing he fail to sustain his case. This was done in the case of Walsh *v.* Sayer, where an action was instituted to recover damages in the sum of $20,000. The court gave judgment for defendant in five per cent. of the sum of $20,000, as an extra allowance, in addition to his usual costs.

I would suggest as the most effectual method of remedying unjust prosecution that the members of the medical profession co-operate with corporations, lumber companies, railroad companies, and all classes who are harassed with unjust suits and get a State law compelling every person instituting such suits to reimburse defendant twenty-five to fifty per cent. of amount of damages claimed in case plaintiff failed to sustain his case. This will prevent ninety per cent. of these senseless prosecutions. If this cannot be accomplished, or seems too harsh, then let there be a statute compelling those who seek remuneration to submit the case to three disinterested physicians, who on investigation, will determine whether there is cause for complaint.

"A profession should be protected that has for its object and end the accomplishment of great good, assuaging of pain, physical and mental, the lengthening out of a precious life, a profession that has produced, in all ages, able self-sacrificing men, and now has within it as noble examples of moral and intellectual manhood, possessing substantial knowledge and practical skill, as ever blessed our earth" (Elwell).

In conclusion, I will say if you expected to hear a triumphant record of the marvellous progress of surgery, or a pæan on my own local surgical achievements, you are disappointed. But I trust that my humble effort at this interesting theme will be of wider interest and of more general benefit.

INFECTIVE PHLEBITIS AS A SEQUEL TO FOLLICULAR TONSILLITIS.

By JOHN TRUMBULL, M.D.,

VALPARAISO, CHILI.

BELIEVERS in antiseptic surgery found their practice on the belief that suppuration is always due to the presence of certain microscopic organisms, which by spray, irrigation, asepsis of instruments and operating hands, drainage, and dressings, they have sought to exclude or deprive of the fluids in which they might multiply. Methods for securing cleanliness, in its broadest sense, may vary with every operator, the spray be set aside, irrigation with chemical disinfectants or germicides be supplanted by the use of pure water, but the aims of Listerism to exclude germs hold good.

In operative procedure surgical thought would certainly say that without septic bacteria suppuration does not take place. And if the logic of surgical experience and biological research be legitimately carried out, we must concede that such bacteria are essential to the formation of matter anywhere in the body. As Rindfleisch, Birch-Hirschfeld, Klebs, and others have shown, where pus is formed infective microphytes exist; and if this process begin within the circulatory system, or elsewhere, it is our task to seek to discover how and why they are there.

Pyæmia in the main belongs to the domain of surgery, but is occasionally met with in internal medicine. Such cases become doubly interesting to those who are compelled to regard them as dependent on an infection arising from the presence within the body of certain micrococci. To explain septic fever, infective thrombi, and secondary abscesses, the existence of septic bacteria is assumed. These generally have gained access, first to, and then through, some wound. With pyæmic symptoms one naturally looks, therefore, for a breach of surface. Failing this, communication with the exterior of the body is generally found in connection with the local diseases which occasionally give rise to pyæmic infection in medical practice. In the pyæmia that follows parturition, that has its origin in diseases of the urinary tract or those about the alimentary canal, or in carious disease of the bones of the ear, the various channels of communication with the exterior of the body, in these cases, account for the possible presence of infective microscopic organisms in the point of departure for the general process. But those cases which post mortem examinations set down as having their origin in disease of the bony framework of the body, or within the vascular system, are more difficult of explanation. Both of these latter, one would expect, must depend on the presence of septic germs in the

blood; for where a general infection starts from an acute osteomyelitis or abscess of a bone, it can only be through the vascular system that the infective microphytes reach their chosen field for colonization. That being so, the question resolves itself into accounting for the presence of these offensive germs in the blood alone. Koch says that "never, in a single instance," has he found micro-organisms in normal blood, and concludes therefore that they are not present. Still, if present in an abscess of the liver, they must have reached that organ through the blood-vessels, even though an examination fail to disclose any circulating in the blood. But if that which makes possible a purulent focus in the liver, or tibia, reached its nidus from the blood circulating about it, we must grant that these germs can pass through the capillary walls. Klebs has traced the progress of gogglöa not only through the interspaces of the cellular tissue, but has found them penetrating through the eroded wall of a vein. This is only a step from conceding that through the pulmonary tissues they may likewise pass into the body, and the occasional occurrence in chronic valvular disease of ulcerative endocarditis after pneumonia, points to the presence of septic micrococci in the blood, whose entrance was effected through the pulmonary tissues in a disease attributed itself to infection. Whether ordinarily, along with the interchange of gases, the different microphytes pass through the alveolar tissues and capillary walls, one is not in a position to claim; yet their presence in the air-cells, and readiness to avail themselves of every opportunity, would seem to be shown by the well known fact that croupous pneumonia occasionally follows traumatism of the chest, when, as may be supposed, the injury weakens the resistive power of the tissues against germs already there, or almost immediately received and harbored. The general infection which so universally follows exposure to certain specific diseases, in those whose immunity is not assured by having been already attacked, points often to the same method of infection. How else can one explain the facts, testified to by Murchison and other observers, of typhus following immediately on exposure, where "the patient having been conscious of an offensive odor proceeding from a case with which he had come in contact, was at once attacked with headache, prostration, nausea, rigors; and all the other symptoms developed in due course?" Authentic outbreaks of typhoid fever plainly show that the causative agent is carried by currents of air; and small-pox, scarlatina, measles, whooping-cough, etc., are undoubtedly thus transmitted, and probably enter through the pulmonary tissues or some portion of the mucous tract of the organs of respiration or alimentation. And if the germs of these specific diseases can thus find the portals admitting them to the precincts of the body, we can scarcely decline to recognize that thus the intruder bent on septic mischief may gain admittance.

While the respiratory tract does not seem to require any appreciable breach of surface to permit of parasitic organisms securing a passage into the human circulation, the skin, so far as we know, does. If whole, it is protective; but once broken, it offers a ready port of entry to obnoxious microscopic immigrants anxious to settle, and by their thrifty multiplication threaten the stability of the central forces of human life.

The mucous surfaces of the genito-urinary organs have a freer superficial circulation, and, I doubt, not often allow of infection without any erosion of surface. Syphilis is, I fancy, often planted where there is no scratch, and secures its footing in consequence of the active circulation accompanying erection. The gonococcus will pre-empt any urethral surface if given a chance of sleeping there over night to enable him to enter a claim next morning. Some may regard this as a purely local infection, though at times the febrile manifestations accompanying it would indicate a more general process, and the articular complications, with occasional pyæmia resulting at times in this disease, show what a urethral surface may expose one to; or the line of travel may be by extension to the bladder, ureters, pelves of the kidneys, and so lead to general septic infection. We therefore recognize the genito-urinary tract as offering abundant opportunity for septic infection from it as a distributing centre, or even, as in some cases, of malignant endocarditis, providing the requisites for the entrance of the streptococcus to light up infective foci on the curtains of the valves.

We still have to consider the mucous surface of the alimentary canal, and here we find that we have general specific diseases—colitis, enteritis, scarlet fever, diphtheria, and follicular tonsillitis—having an inherent right, as it were, to claim and occupy particular portions of this tract. The question frequently recurs: Do not these limited local inflammatory processes mark the site of entrance of these germs, as the indurated sore does that of syphilitic infection? But the germs that cause these diseases are not the spherical bacteria of suppuration; yet we find that all of these diseases (and, in fact, all which are classed as specific or infective) have, as complications or sequelæ, suppuration, localized now near, and again at some distance, and even directly or indirectly occasionally leading to pyæmia. In such cases organisms that occasion suppurative processes must have found an entrance into the circulation, and that probably through the site of these local manifestations. All are accompanied by breaches of surface somewhere along the tract of the organs of alimentation, and while these would favor the absorption of micrococci, the general lowering of tone found in all specific diseases provides ofttimes the nidus suitable for the cultivation of spherical bacteria. Abscess of the liver, so frequent in portions of Chili, can almost invariably with us be traced to an antecedent dysentery. Taking an average of five years, in the reports of various hospitals in this country, the mortality from abscess of the liver is 1.8 per cent.; that of dysentery 10.6 per cent. Liver abscess is frequent and to be expected where intestinal inflammatory troubles are rife, and the liver is congested by over-eating of highly stimulating and irritating substances, or by periodic excessive drinking, with subsequent exposure in a climate of marked changes between day and night temperatures. Santiago, in a few hours, has changes of temperature amounting to 20° to 25° C., and here we find the heaviest mortality. In two of her leading hospitals the average mortality from suppurative hepatitis is as high as five per cent. But it is rather the relation between liver abscess and dysentery that I wish to emphasize. This remains very constant. A rise in the curve of dysentery mortality is always accompanied by a similar proportionate rise in the liver abscess mortality, and *vice versa;* while pathological investigations confirm this view as to a causative relation, and intestinal ulcers, or cicatrices of such, are generally found. Attention is sometimes strikingly called also, in fatal cases of operation, by the reappearance of bloody dysenteric discharges.

The drainage from Peyer's patches being along the lymphatic spaces, and not to the liver, it is not surprising that typhoid does not lead to suppurative hepatitis; but enteritis has among its complications or sequelæ suppuration of the parotid gland, ostitis, and periostitis.

Scarlet fever often leads to otitis media, though here the Eustachian tube can explain extension to that locality, while the breaking down of glands in the neck and elsewhere must be explained in a different way.

We, alas, know too well the septic intoxication that accompanies diphtheria, though, even when it is not so overwhelming, yet after-troubles of a suppurative nature often manifest themselves.

The dividing line between this and follicular tonsillitis is very indistinct. Both I have found contagious and demanding seclusion to prevent spreading of the disease. The majority of cases are easy to differentiate, while at times, where follicular tonsillitis is not punctate, we have not always a film of easily recognizable pultaceous secretion, but what leaves one in serious doubt as to whether

the case be not one of true diphtheria, though it does not extend beyond the limit of the tonsils. The article of Dr. Boucsein, in a recent number of the *American Journal of the Medical Sciences*, clearly recognizes this as an infective disease, and mentions a number of sequelæ. He says also that "A. Fränkel calls attention to the possibility of general septic infection originating in the tonsil." What begins apparently as a follicular tonsillitis occasionally results in suppuration in or about the gland itself. In quinsy, therefore, we have the introduction of septic bacteria into the deeper or surrounding portions of the tonsils, and the absorption may then be along the lymphatic spaces; but the active local circulation, attested by the visible congestion of the parts, renders absorption by the blood-vessels possible and probable. If we recognize the possibility of entrance through such a track, abeyance of objective symptoms may be explained by the absence of a suitable nidus. Micrococci are indispensable, and as much so a base of operation. The two factors are requisite, and in infective diseases we not only have the opportunity of entrance given to the spherical bacteria, but, further, the lowering of the vital forces makes possible the second essential. I have seen pyæmia occur in carbuncle after the healing process had advanced so far that the thickly matted layer of cells which the microscopic section of a healing granulating wound shows to exist, would prove as effectual a barrier as an unbroken epithelial surface. It seems to me, in this and like cases, that entrance must have been gained before such a protective wall was built by nature; and that, having earlier sought and gained admittance, these septic bacteria retained their vitality until the chance of squatting and breeding an army to storm the citadel of human life was offered. Such, I take it, occurred in the accompanying clinical case, which is reported as a sequel to follicular tonsillitis. I can find no other solution of the question which at once presented itself: From where did this local inflammation receive its infective properties? The process began in the dilated veins, and thence extended to the surrounding cellular tissue, and scattered throughout the body groups of organisms capable of occasioning destructive processes wherever carried and lodged; but those germs which charged the original clots with forces capable of setting up infective disintegration probably entered the circulation through the tonsils, retained their vitality while travelling about the blood-vessels until the opportunity was given them to locate, multiply, undermine the constitution, and finally extinguish the life of the individual.

Mrs. C——, fifty-four years of age, suffered from "swelling of the feet and legs," the cause of which I was asked to discover at the beginning of 1889. There was no functional disturbance to be detected, and careful examination led to the exclusion of its dependence on cardiac, pulmonary, renal, or hepatic disease. From the birth of her first child she had noticed progressive enlargement of the veins, and both internal saphenous veins were found tortuous and knotted throughout their length. The local interference with the return of the venous blood was sufficient to account for the œdema; and measurements having been taken, elastic stockings were ordered from the States and received. These gave great relief, but she found them "cold," and against advice discontinued their use until the return of summer weather.

On September 9th I was called to see my patient for chilly sensations, which had been followed by high fever and severe pains in limbs, back, and head. A general examination again showed there was no abnormal condition of either the heart or lungs; but that she was down with follicular tonsillitis. This was unusually severe, but ran its course in four or five days, so that she was able to be about again, though feeling weak and miserable. Tonics were prescribed, and on the 17th, calling to see how convalescence had progressed, mention was made of several painful discolored spots in the left calf, which, she assured me, were like what she had had on the thighs a couple of years previous—erythema nodosum. She hardly thought them worth any attention but consented to my seeing them. On the inner side of the calf three or four of the bunches of dilated veins I found dusky, tender, and nodular. There was no induration or tenderness along the course of the saphena, so a local adhesive phlebitis, which might prove beneficial, being considered probable, rest in bed, with elevation of the limb and the application of lead-water lotions, was advised.

Early the next morning an urgent message reached me. The evening before a heavy chill had occurred, and when seen the patient had a flushed face with a bounding pulse of 120, and temperature of 39° C. She complained of vomiting, headache, and general malaise, with pain localized in the left calf, which was swollen, hot, and showed a cellulitis extending over a surface the size of the palm surrounding the dusky obstructed veins of the previous day. Antifebrile and tonic treatment, with the local application of poppyhead fomentations was begun at once. The husband was advised that she was dangerously ill, and a consultation was asked for, as, from fortunately having seen the trouble in its incipiency, a diagnosis of infective phlebitis, with general septic infection, was surmised.

September 19th.—Yesterday afternoon a second heavy rigor came on, followed by renewed elevation of temperature, quickened pulse and respirations, and marked depression. Prostration extreme, and only explainable on the basis of a general infection. Temperature continues high, unless brought down by repeated gramme doses of antipyrine. Tongue clean and dry, though vomiting continues. Examination of the chest discloses fine subcrepitant and moist râles in scattered spots over both backs. Complains of intense headache and deep-seated pain in the leg. The cellulitis is not extending, and free incisions were advised against, as probably the deeper veins could not be opened and general infection had occurred.

September 20th.—Yesterday another rigor. Temperature rose to 41° C. Acute pain in right shoulder and elbow followed, and continued throughout. Later on the ankle and smaller joints of the right foot became tender and acutely painful on the slightest motion, though without swelling or heat. To-day there is tenderness along the femoral vein, while the local inflammation shows no sign of increasing. The pulmonary mischief has extended. Dulness is now present over the lower half of both lungs, with bronchial breathing and subcrepitant râles, and added friction-sounds on the left. Left front also implicated. Respirations, 38; pulse, 120, failing despite digitalis, ammonia, and nux vomica; temperature, according to the use of phenacetin, between 38° and 40.5° C. Urine contains albumin, and is stained with biliary coloring matter.

September 22d.—Patient sunken in bed and unable to assist herself in any way. Aspect cyanotic, with pronounced jaundice of conjunctivæ and face. Dull of hearing. Temperature unaltered; pulse feebler and rising in frequency.

September 24th.—Condition rapidly changing for the worse in every way, though no new focus of infection has declared itself. Weakness is increasing, as shown by inability to void urine and involuntary dejections. Pulse varying but little; respirations increased to 44, and no cough present, even while the pulmonary foci are extending in area. Leg has become painful again, and the swelling since last evening, when it began, has doubled the size of the limb. Local condition demanding interference, yet the hopelessness of the case contra-indicated surgical procedure, as when it arose the temperature, after a chill, had fallen to 37° C., while the pulse continued upward to 160, the discrepancy between pulse and temperature indicating overwhelming poisoning.

September 27th.—For a couple of days from date of last note the temperature remained between normal and 38° C., and pulse fell to 136, still failure of forces and general insensibility deepened. Death to-day was quiet, after thirty-six hours of rising and falling of the thyroid, tracheal râles and heaviness passing slowly into stupor.

Clinical Department.

DRY GANGRENE IN A CHILD.

By T. C. WALLACE, M.D.,

CAMBRIDGE, N. Y.

In the MEDICAL RECORD for July 5th, the "Case of Dry Gangrene in a Boy Two and a Half Years of Age," by Dr. Kelley, of Winchester, Ind., prompts me to relate the following:

Georgiana G——, aged twenty months, had been quite sick for several days with measles, under the care of an intelligent practitioner, and was fairly convalescent. Early in the morning of April 12, 1886 (after a comfortable night), her right leg, up to and including the ankle, was found to be very cold. She lay in a crib-bed and it was thought she had protruded her foot between the slats from under the bedclothes. The leg was wrapped in a warm flannel and replaced in bed, and no more thought of the matter until, after a few hours, it was examined and found to be still cold. More energetic means of warming the limb were resorted to—friction, hot water in bottles, etc., but all of no avail. The child did not seem in any way worse, made no manifestation of pain, and appeared to suffer no discomfort. It was simply impossible to warm that foot, although every effort was made all the day and the succeeding night. During next day the foot assumed a livid hue, which gradually deepened in color. Next morning (April 14th) I was called. The limb was of death-like coldness up to and above the ankle, of a mottled mahogany color, darker at the toes and gradually growing lighter toward the ankle, where was a well-defined edge indicating, I thought, the future line of demarcation. I informed the parents the trouble was due to embolism (explaining that to them), and, excepting proper measures to strengthen the child, nothing could be done to remedy the trouble; that we must wait until the line of demarcation was clearly established, and that the foot would probably have to be amputated above the ankle. Next morning I found the big toe and the one next to it in a state of gangrene, and a large gangrened spot under the heel. The dark color near front of foot more profound. To my surprise, the color above and around the ankle was much more natural and the parts warmer, in fact of normal warmth. The embolus had either been forced further down in the artery, or the collateral circulation had become more established. It was then hoped that, except for gangrened spot under the heel, the heel itself might be saved by either Syme's or Pirogoff's amputation. In a few days all the toes underwent gangrene—true senile gangrene, dry, black, and odorless. This gradually spread until the whole foot nearly to the tarsus was in a like condition. The progress of the case was slow. The circulation about the ankle gradually becoming more active. After two or three demarcation lines were plainly indicated the true line at last formed, just anterior to the tarso-metatarsal joints, and on June 26th I amputated through those joints. Happily the gangrene under the heel included only the soft parts, and the periosteum was not involved. The stump healed satisfactorily, but *very, very slowly*. The child's physical condition was good throughout the whole progress of the case, and she put on a large amount of flesh. She has enjoyed uninterrupted health ever since. Doubtless, owing to the original embolism, the limb has never grown equally with its fellow. Its temperature is perfectly normal, but its contour is not so well developed, nor does it grow in length so fast. It is now seven-eighths of an inch the shortest.

This being the only case of so-called dry gangrene in a young child I had met with, in an active practice of over thirty-six years, convinced me of its rarity. Conversation with brother practitioners of extensive experience elicited the fact that it was equally novel to them, none having seen or heard of such a case. I wrote to the late Professor Frank H. Hamilton, and to Professor D. Hayes Agnew, who each replied they had never seen spontaneous gangrene in a young child. I searched every authority I could get access to, and aside from a general statement "that such cases are occasionally recorded in children under ten years," I could find but two cases recorded: "Pathological Society Transactions," vol. xx., an account of a case of gangrene in an infant aged eleven months. "The little patient was recovering from an attack of measles, when the left foot became black, hard, and dry; and on the thirty-second day dropped off at the ankle-joint, leaving the ends of the tibia and fibula protruding. A proper stump was then formed and the child made an excellent recovery." Holmes, last edition, vol. v., in describing surgical diseases of children, relates a fatal case in a child (age not given) just recovering from measles. It is certainly singular that these two cases, as well as my own, should not only have had the *measles*, but all three were *convalescing* therefrom. I also wrote a query to four medical journals, requesting anyone who knew of such a case to correspond with me. The only reply received was from Dr. Nickerson, of Meriden, Conn., who gave the following interesting history: "Three children in one family were almost simultaneously attacked by a severe remittent fever, accompanied, on the third day, by smoky urine which proved to be half blood. One recovered in a few days, without any troublesome sequelæ. One had acute Bright's with uræmic convulsions and a final subsidence of symptoms two years afterward. The third, a child of two years and four months, was seemingly convalescent. The fever had ceased, the urine was fast clearing up, and the child was sitting up in bed playing when I called in the evening. On my morning visit my attention was called to the toes on one foot, which I found quite black, or, in other words, dry gangrene; this rapidly extended up the leg and thigh, and before it died the entire limb, to the junction with the trunk, was perfectly black."

Dr. Nickerson and Professor A. L. Loomis were both of the opinion that the three cases just mentioned were primarily cases of ulcerative endocarditis.

REPRODUCTION OF BONE.

By R. W. ERWIN, M.D.,

BAY CITY, MICH.

Otto N——, aged nine to ten, German parentage, healthy. About a year prior to his application for treatment he stepped upon a nail, causing a puncture-wound of the right foot near the middle of the sole. The puncture was superficial, and disappeared in a few days. Some weeks later soreness came on, and continued with intermissions to the time of his consulting me. Examination revealed a slight ridging of two lines in width by an inch or more in length over the fourth metatarsal bone. There was no swelling or discoloration of the foot, and tenderness only in moderate degree. The appearances were so negative that a doctor had diagnosed rheumatism and prescribed liniment. A free incision was made through the periosteum, October 7, 1887, with a view of relieving what was believed to be chronic periostitis. The knife penetrated the bone, and dry ostitis was found to exist—the bone being very brittle and soft. Poultices were ordered, and compound syrup hypophosphites prescribed. On October 18th, assisted by Drs. W. E. Vaughan and Ambrose, of this city, I enlarged the former incision and exsected the bone. It was very friable, and easily picked out with the fingers and elevator. When this was removed the adjacent metatarsal bones were discovered to be in the same condition. These were removed and the work continued till all the bones of the foot and ankle had been taken away, except the metatarsal of the great toe and the toe-bones (phalanges). To facilitate the opera-

tion a vertical incision was made over the os calcis behind. The periosteum was left in each instance, as far as possible. The exsection embraced the second, third, fourth, and fifth metatarsal bones, the cuboid, internal, middle, and external cuneiform, scaphoid, astragalus, and os calcis bones. The operation lasted a little over an hour, and when completed many little pieces of bone, the size of a pinhead to that of a grain of wheat, which had dropped off, lay in the wound. These were washed and brushed out as far as possible. Nature had made an attempt toward repair at several points among the tarsal bones, as evidenced by deposits of new bone—notably at the under surface of the os calcis. This was removed, since the separation could not be effected. The wound being cleansed as stated, was dressed by inserting longitudinally a large-sized drainage-tube, and the cavity about it filled with oakum saturated with balsam of Peru diluted with glycerine. The foot was then bandaged, using antiseptic gauze, and supported by a felt-splint. On the third day the oakum was removed, and replaced with fresh. The balsam was applied by pouring into the tube, and drawing it through the wound daily. This was prefaced with a thorough washing with listerine and warm water, and the gentle moving to and fro of the tube, with a view to cleansing the wound and getting rid of the small bone fragments. The parents were intelligent, and gave valuable assistance in this and the subsequent care of the foot. The pluck of the boy was not without advantage also. Ten days after the operation, all fear of septic trouble having vanished, a plaster-of-Paris splint was applied with fenestra about the drainage-tube. As time progressed the tube was reduced in size. At the end of five months it was removed, and a skein of carbolized silk inserted. Each day this was made fresh by pulling through and cutting away the soiled part. The quantity of silk was rapidly reduced, owing to absence of suppuration, to three or four strands, these being continued till the bone closed about them. The following June or July the last thread was removed. Recovery was complete, new bone having formed throughout. The plaster-splint was continued a few months longer, the boy walking upon the foot, supported by a crutch, the latter more as a check against accident than from need of support. Eighteen months have since elapsed, the boy running and playing with other boys upon the street, the foot being as sound, apparently, as ever. In that period neither pain nor swelling, nor other indications of trouble have appeared. There is some motion of the ankle, which will increase. The distance from the ankle to the floor is shortened, while the transverse diameter of the heel and tarsus is increased. The very slight shortening of the limb is scarcely perceptible in his walk, and might be relieved with a cork sole. He declines such aid, using an ordinary shoe in the heel of which he places a little padding.

Since writing the above his father reports the foot is perfectly sound, and free from any tenderness.

FLOATING KIDNEY.

By B. SCHEINKMAN, M.D.,

NEW YORK.

On June 9, 1890, I was called to see a patient suffering apparently from an attack of acute indigestion. After having failed to relieve the symptoms with my usual treatment, I submitted her to a more thorough examination, and on manipulating the abdomen I accidentally discovered a hard, oblong, and very freely movable tumor in the right lumbar region, on a line midway between the anterior-superior spinous process of the ilium and the umbilicus immediately beneath the abdominal wall. On a closer examination it presented the following features: it was about six inches in its long diameter and about three and a half inches transversely; kidney-shaped, its upper extremity being round and thick, while the lower was thinner and more conical in shape. I could grasp it with my hand so as to embrace over two-thirds of its posterior surface (through the abdominal wall). On slightly pressing it the patient felt a peculiar sickening sensation under the sternum, at about the cardiac end of the stomach, which she could not describe. The patient was a lady about forty-eight years of age, having had twelve children, of a healthy constitution, with a good family history. She told me she had noticed this tumor during the last eight years, it having first made its appearance after a confinement. She never paid any attention to it, as it never caused her any trouble, and would usually disappear for weeks after having been noticed for a day or two. From its very defined and accurate kidney-shape, and by exclusion, I am almost convinced that the tumor was a movable or floating kidney.

WOUND OF LEFT VOCAL CORD.

By F. SEMELEDER, M.D.,

CITY OF MEXICO.

This strange, and probably unique, case was lately observed by me. A wounded woman was picked up by the police and taken to the Municipal Hospital, where by the courteousness of Dr. T. Nuñez, the director, and Dr. Zarraga, I had the opportunity to see and examine her.

The woman had been stabbed with a stiletto which entered the left side of her neck, about three-quarters of an inch from the median line, between the hyoid bone and the thyroid cartilage. The wound was one inch long, and had all the characteristics of a cut wound, hardly any hemorrhage. The patient had an easy and speedy recovery, but she remained hoarse.

Laryngoscopical examination revealed an inflamed condition of pharynx and upper part of larynx, and a cicatrized wound, dividing in a transverse direction the left vocal cord, between its median and posterior thirds, near the insertion to the processus vocalis; this causes insufficient tension and imperfect occlusion, and is a perpetual cause of hoarseness, never to be removed.

Tumor of the Cornea in an Old Man.—At a meeting of the Ophthalmological Society of the United Kingdom, on May 1, 1890, Dr. Benson, of Dublin, reported a case of probable fibroma in a man seventy-two years of age. The tumor was attached to the upper portion of the left cornea of a blind glaucomatous eye. It measured 5 mm. in its longest diameter, 2 mm. in thickness It was adherent to the surface of the cornea above the centre by 2 or 3 mm. of its thin edge. The eye was said to have been blind for many years, but a few days before the patient came under observation he had knocked it against something, and since the blow had suffered intense pain. There was no evidence of recent injury to the eye. The growth was dissected off the cornea, and was found to consist of fibrous tissue with blood-vessels and cells, the whole being covered with epithelium, except at the margin, where it had been separated from the cornea. It had a dull, lustreless, gray color, and was lenticular in shape. The speaker referred to the great rarity of corneal tumors, and said that he could not discover the cause of the growth in this case.

Long and Hard Driving in Country Practice.—Dr. Charles T. Montgomery, of Glasco, N. Y., a typical general country practitioner, who is the popular physician for a wide district, drove in an ordinary buggy one hundred and seventy-three miles in forty continuous hours without rest save at meals. During this time he saw sixty patients and used only four horses for the work, driving them in pairs. Very few, if any, practitioners can equal this, and yet very many of our good friends in the country of large business have similar strains upon their endurance. Who can beat this record?

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, August 9, 1890.

THE INTERNATIONAL MEDICAL CONGRESS AT BERLIN.

So far as our cabled reports of the present or Tenth International Congress go, it would appear to have been an unqualified success. Of course, it is open to question whether, in a strictly scientific sense, much good ever comes of these huge and unwieldy medical gatherings. The true science of medicine is modest and of a retiring disposition. It likes to do its work in quiet corners. It makes simple announcements of the results of its labor. Not so with the frequenters and hangers-on of congresses. What would hopelessly disturb pure science, is the very life-blood and delight of pseudo-science. The former despises what the latter revels in.

Every congress thus far has suffered from the polyglot clamor of those who go to blow their own trumpets, those who are mere medical politicians, wire-pullers, open advertisers, brazen-faced priority-claimers, and a host of people who have their little axes to grind. True merit too often stays at home. Thus it has happened that important medical discoveries have never been first announced before the babel of these triennial mass-meetings.

But the consultation-hunters, the claim-everything-agents, the notoriety-promoters, the enterprising hob-nobbers, the "strictly-business" doctors, and those little fellows who so dearly love to rub up against the big fellows—these and others like them are always out in full force.

The real importance and undisputed popularity of international medical congresses are chiefly found in the social features that accompany them. The solidarity of our profession is thereby brought home to representatives of all civilized nations. And the world at large may be confidently invited to witness a demonstration of international good-will, which should go far toward fostering humanitarian, as opposed to warlike instincts. It is in these larger aspects that medical congresses deserve the encouragement of unflagging interest and serious attention.

In point of mere numbers, the Berlin Congress will have to take the first rank, nearly eight thousand physicians being in attendance. As to the relative value of the numerous papers read before it, judgment will have to be suspended until the fuller reports permit adequate comparison. A formidably large American, or German-American, contingent was present. But we miss among the numbers many of the names that we have reason to be most proud of. New York naturally sent the greatest number of physicians, and many communications were read by them in the various sections.

Although this will be ascribed to numerical pre-eminence alone, we may nevertheless feel justly proud of the prominence assumed at this congress by the leading city of the Western continent.

The banquets, entertainments, and excursions were not all that could have been desired by exacting ones. But the ruffianly stampeding that marred some of the Washington festivities was nowhere to be seen. All things considered, we may as well admit that "they do those things better in Germany."

A proposition to hold the next Congress at St. Petersburg, in 1893, was rejected, and the place of meeting decided upon was Rome.

THE EXECUTION BY ELECTRICITY.

THE lengthened agony of suspense regarding the efficiency of electricity as a means of executing criminals has been finally terminated in the legal killing of Kemmler. As was reasonably anticipated, death was instantaneous, and, so far as can be judged, the unfortunate subject of the experiment died without pain. The spectacle presented was, however, by no means edifying to such as hope for improvements of old methods.

Although science has triumphed, the question of the humanity of the act is still an open one. But shall we call it a triumph when the object obtained was the killing of a fellow-being? Heretofore the proudest claim of science has been to save, or at least to prolong, human life, and insure for its possessor the greatest enjoyment of its many bounties. In this instance it has been plainly diverted from its course, under a paradoxical plea of high humanity. And yet men of science have lent their best efforts in this direction to humor the whims of a few cranks and "world betterers," who imagined they could make legal murder a fine art, and enforce into it an element of sentimentality which might rob it of its atrocity.

While we allow that electricity has been a success as far as the killing is concerned, we must also admit that we have gained little, if anything, over the ordinary method of execution by hanging. The preliminaries of electrothanasia are far from pleasant to contemplate. Alongside of those for hanging they are pretentiously horrible. There is something more than weird in the preparation of the machine, the deliberate fixation of the victim, the adjustment of the electrode, and the "thousand deaths in contemplating one," which more than offsets the quick though damnable "taking off." The horrors, though hidden, are nevertheless felt. There is something else to be thought of than the mere quickness of death. While the latter might have been triumphantly done, the agony of the criminal during the preparations must be terrible as compared with that of hanging. It becomes a serious question if humanity is not paying too dear a price for instantaneous demolition. The awe and mystery of death are intensified a thousand-fold in anticipation of what this instrument of subtle power may do as compared with

either the noose or the rope, the grip of the garroter, the smart of the knot, the bore of the bullet, or the chop of the axe. And yet to harness the lightning and bolt it through a human body is thought to be one of the advances of the nineteenth century.

The experiences in the Kemmler case, in spite of all the precautions taken, have shown many difficulties in the way of a general adoption of the method. It is far from simple in its application. It requires elaborate and careful preparation; it multiplies machinery, which without expert manipulation is liable to fail in its working and bring about disastrous results; it may be a source of danger to the executioners and spectators; it increases the expense of executions; but, worse than all, in the necessary preparation of the victim there is crowded upon him in a few seconds an amount of horror and suspense which has no comparison with any other form of rapid demolition, save those of being thrust into the muzzle of a loaded cannon or tied to a dynamite bomb.

When it is assumed that the ends of justice and humanity are reached by the contrivance in question, and when it must be admitted that even this method cannot be divested either of cruelty or barbarity, the way seems to be open for the discussion of the abolition of capital punishment altogether.

From physical, humanitarian, and judicial stand-points, the time is ripe for its consideration. We venture to predict that public opinion will soon banish the death-chair, as it has done the rope, and that imprisonment for life will be the only proper punishment meted to a murderer. This is, indeed, the only rational method which science, justice, and religion can consistently recommend. The death-chair will yet be the altar from which this doctrine will be preached.

NON-MEDICAL CORONERS.

It is a reproach to medicine that politicians are, as a rule, appointed or elected coroners while all their important technical work has necessarily to be done by physicians. The *Journal of the American Medical Association* upon this point says: "In Illinois all the evils of the political coroner are most pronounced, and, doubtless, any effort that may be made to correct them will meet with determined opposition from the office-holding class. The laws governing coroners in Illinois are but a prototype of those in a majority of the States; only a few having so far made any effort to reform this relic of the Middle Ages. The Chicago Medico-Legal Society nearly two years ago appointed a committee that submitted an able report summarizing the abuses of the present system and urging the adoption of the Massachusetts law."

Unfortunately, it will be necessary in this State to change the Constitution in order to get rid of the coroner system. But such a change ought to be made.

THE DOSE OF THE ALKALOIDS OF HYOSCYAMUS.

A remarkable case of supposed poisoning by hyoscyamine recently occurred in Brooklyn. A patient suffered from alcoholism and its accompanying excitement and insomnia. He was prescribed, it is stated, capsules containing an eighth of a grain of amorphous hyoscyamine. Two doses were taken, the second one two hours after the first, and immediately succeeding the latter dose the patient began to show symptoms of hyoscyamine poisoning and he died in a few hours. It is asserted that the investigation showed that the crystalline hyoscyamine was used instead of the amorphous, hence the toxic effects. The drug-clerk who put up the capsules was arrested; by some mistake the body was embalmed, so that the autopsy showed nothing except, perhaps, a hypertrophic cirrhosis. It is also stated that the doctor's original prescription has disappeared. The drug-clerk asserts that he put up the medicine just as it was written and there is no proof to the contrary, except that of a circumstantial character.

Even if there were, however, it is doubtful if the drug-clerk could be made responsible. For there is still the greatest discrepancy in standard text-books as to the dosage of the various alkaloids of hyoscyamus. Brunton's work, published last year, makes the astonishing statement that the dose of hyoscyamine is from gr. $\frac{1}{60}$ to gr. 1. If a professor of pharmacology says this, what can one expect of a drug-clerk? Several text-books also say that amorphous hyoscyamine is identical with hyoscine; and this is a serious error. Yet even if it were true, cases are reported in which a dose of gr. $\frac{1}{5}$ of hyoscine has been given without serious results.

The great disagreement with regard to the dose and toxicity of the hyoscyamus alkaloids is shown in the following notes:

Lemoine (1889) gives the dose of hyoscyamine as gr. $\frac{1}{60}$ to $\frac{1}{120}$.

Doses of gr. $\frac{1}{40}$ and gr. $\frac{1}{10}$ have caused toxic but not fatal symptoms according to Drs. West and Thompson.

The dose of hyoscyamine is the same as that of atropine, according to Nothnagel and Rossbach.

The dose of hyoscyamine sulphate is gr. $\frac{1}{60}$ to gr. 1, says Brunton, in 1889.

Hyoscyamine has maximum dose of gr. $\frac{1}{3}$, according to Gnauck, 1881; that of hyoscine is gr. $\frac{1}{300}$.

The U. S. Dispensatory gives the initial dose of hyoscyamine sulphate as gr. $\frac{1}{60}$. That of hyoscine is not given.

The dose of hyoscine, according to Budder, in 1888, is gr. $\frac{1}{160}$.

According to S. Fischer it is gr. $\frac{1}{120}$ to $\frac{1}{60}$.

A dose of gr. $\frac{1}{5}$ was given by mistake without bad effects by Dr. W. H. H. Githens.

Dr. King has used hyoscine in doses of gr. $\frac{1}{124}$ to gr. $\frac{1}{85}$.

Toxic symptoms were caused by doses of gr. $\frac{1}{50}$ and $\frac{1}{75}$, also by a dose of gr. $\frac{1}{100}$ (Prentiss).

The maximum dose of hyoscine is gr. $\frac{1}{50}$, according to Dornblüth, 1889.

Cases of non-fatal poisoning from doses of gr. $\frac{1}{25}$, $\frac{1}{60}$, and gr. $\frac{1}{120}$ are reported by Drs. S. W. Morton, J. S. Gibb, and W. A. Edwards.

E. B. Potter thinks doses of gr. $\frac{1}{20}$ to $\frac{1}{15}$ are safe.

In all the above references nothing is said about amorphous hyoscyamine. This is a mixture of hyoscine with other substances, among them being a small amount of hyoscyamine. Its effects are more of a hypnotic character than the pure alkaloid and it has been extensively used in this city as a hypnotic. The dose is much larger than that of the pure hyoscine or hyoscyamine.

AN ANTHROPOMETRICAL STUDY OF PROSTITUTION.

THERE is a very prevalent opinion, and one upheld even by philosophical historians like Lecky, to the effect that prostitution is not only a necessary factor in society but a beneficent and useful one. Prostitution is the gutter through which the brute passions of man are drained away. It is as necessary to society as a sewage system, preventing foul vapors from invading the home. The prostitute is apotheosized as the savior of the family.

Without discussing the merits of this view, it would be well for the philosophers to study the interesting and curious work of Dr. Pauline Tarnowski, entitled "An Anthropometric Study of Prostitutes and Thieves." [1]

Dr. Tarnowski's observations cover a period of four years. They were made upon 150 professional prostitutes received at the Hospital de Kalnikine, and upon 100 female prisoners at Litowski Zamok.

Tarnowski's studies of the prostitutes lead him to the conclusion that the women of this class belong psychically and physically to the degenerate classes, that they are the product of inherited disease and neurotic taints. The making of the prostitute depends upon alcoholic excesses, syphilis, phthisis, etc., and to relieve society of prostitution one needs to attack these vices of modern society. Prostitution, according to our author's view, is not so much the result of man's uncontrollable sexual passions as it is of society's vices in general.

Criminologists find that men commit crimes four or five times as much as women do. The inference that man is five times as criminal and vicious as woman is denied by Tarnowski, who finds that prostitution in woman belongs to the same category of ethical defects as crimes, that female thieves are of the same class as female prostitutes, and that prostitution so levels the criminality that the balance between man and woman is an even one.

Dr. Tarnowski's work contains a great many interesting facts regarding heredity, anthropometry, and mental and physical degenerations. It shows evidences of a painstaking labor and of a purely scientific spirit. We can give, however, but few details, and must content our readers with presenting the most essential of his conclusions.

Professional prostitutes, he says, show a morbid heredity more or less marked. Alcoholism was especially noted, being present in eighty-two per cent. In 50 out of 124 both parents were drunkards. Among 150 prostitutes 95 admitted excesses in alcohol. Phthisis was abnormally frequent among the parents. Among 150 prostitutes 44 had parents who died of this disease, while among 150 honest women only 15 had phthisical ancestry. Hereditary syphilis was established in four per cent.; epilepsy and mental disease were established in over ten per cent. of the parents.

It was also found that prostitutes present in excessive degree the physical signs of degeneration, such as cranial deformations, abnormalities of visage, dental defects, badly shaped or badly placed ears, etc. All these stigmata are more marked in cases where the mother was an inebriate.

Mentally the prostitute also shows an enfeeblement of the intelligence and especially of the moral sense. Most of them like their calling, and if withdrawn from it they return as soon as they can. They were found to have menstruated earlier than the average woman, to have shown a premature development of the sexual sense, and like the degenerate classes generally, to be relatively sterile. Among 150 prostitutes 92 had been infected with syphilis.

Despite all efforts to elevate and improve the masses, the number of prostitutes will constantly receive new recruits, says Tarnowski, as long as the causes of it exist, viz., the abuse of alcohol, the enfeebling diatheses, phthisis, syphilis, and the grand neuroses and psychoses. Those who would attempt the radical cure of prostitution must work to lessen these factors in its causation. The prostitute is a special and morbid type of humanity, the result of its vices not of its necessities.

Dr. Tarnowski has studied the women faithfully and scientifically. Cannot some one now undertake to measure the heads, record the facial angles, photograph the faces, and note the position and shape of the ears of the male prostitutes who habitually frequent the houses of prostitution and give the main support to this unfortunate class? We should find, no doubt, among 150 male debauchees the same proportion of bad heredity, misshaped skull, and debased moral sense. Dr. Tarnowsky does not study this interesting phase of the question. It takes two to construct the prostitute.

CLOSTRIDIAL NEPHRITIS—A NEW FORM OF BRIGHT'S DISEASE.

DR. F. V. HOPKINS, of San Francisco, contributes an original, and apparently carefully carried out, bacteriological research to the *Pacific Medical Journal*. It is based upon the observation of a case of chronic nephritis, due, as he believes, to a peculiar micro-organism which he terms "Clostridium renale." The description of the germ is as follows:

Circular cocci, 1.27 μ in diameter; rods, with rounded ends averaging .6 μ in thickness by 3 μ in length, sometimes enlarging characteristically to bear a sporangium, oval in form, and measuring 1.27×2.5 μ. Spores circular, .42 μ in diameter. Filaments of indeterminate length, sometimes .6 μ thick throughout their whole extent, at others, 1.7 μ at one end and tapering at the other into branches, whose ends separate by fission into the usual round-ended rods .6 μ thick by 3 μ long. Non-motile, pathogenic, infests the blood and is carried by it to the capillaries of the principal organs, which it obstructs.

This organism produces a chronic affection of the kidneys and other organs of the body, characterized by nervousness, sleeplessness, flatulent dyspepsia, albuminuria, dropsy, dyspnœa, and heart-failure. The occurrence of the germs in the urine, free and in casts, is its pathognomonic symptom.

The particular case in question upon which the description is based was that of a woman who suffered from nervous depression, dyspepsia, insomnia, and cardiac weakness. Her urine contained various peculiar

forms of albumin. Delafield gives tests by which six different varieties of albumin are distinguished. Dr. Hopkins' patient passed still other varieties than these. We are not told the specific gravity of the urine, its daily amount, or that of the albumin, and in this and some other respects there seems to be a lack of careful clinical observation. Casts were found, however, which were composed entirely of bacteria, occurring in the form of rods with rounded ends.

These bacteria were cultivated under proper precautions, and inoculations were made in rabbits with the result, invariably, of causing albuminuria, dropsy, and death, with the bacteria in the kidneys and other tissues.

The patient died, but no autopsy could be made.

Dr. Hopkins' claim to have discovered a new and peculiar form of nephritis cannot be said to be absolutely established, but he has done a service in calling attention to the importance of the bacteriological study of renal casts. The similar studies in bacteriological nephritis which have been made by others are given by the author, thus :

Babes, in Cornil et Babes' "Bacteriologie," p. 373, Figs. 197, 198, has described the "Bacille de la nephrite bacterieuse." "Cylindrical rods, with rounded ends 0.8 μ to 1 μ thick, and of very variable length, sometimes 1.6 μ to 2 μ and sometimes 20 to 50 μ, and sometimes curved." "Habitat, in the urine and renal tissue of patients with diseased kidneys."

In 1880 Dr. Ballard reported a case of meat-poisoning that occurred at Welbeck, Nottinghamshire, England. Four died out of seventy-two that were affected. Bacilli were found plugging the capillaries of the Malpighian bodies in the kidney, though the symptoms were choleraic. The tube-casts were of the hyaline variety (Klein, "Micro-organisms and Disease," pp. 122–125).

The bacilli of swine-plague also attack the Malpighian corpuscles, but here the bacilli occupy the capsule, the capillaries being plugged with hyaline matter (*Ibid.*, p. 133).

Again, the Bacillus anthracis may completely plug the capillaries of the glomeruli and of the renal cortex (*Ibid.*, Fig. 87, p. 160).

Bacillus tuberculosis also can obstruct the blood-vessels of the kidney (*Ibid.*, Fig. 92, p. 171).

The fungi Aspergillus flavescens and A. fumigatus, when injected into the peritoneum of rabbits, proved fatal by forming foci in the kidneys and other organs (*Ibid.*, p. 200; Lichtheim, in *Berlin. klin. Woch.*, 9 and 10, 1882).

Letzerich describes twenty-five cases of an acute dropsy of young persons, which he calls "nephritis bacillosa interstitialis primaria." This disease lasts from two to six weeks, and is due to bacilli which swarm in the urine. Twelve rabbits inoculated with pure cultures of these bacilli developed ascites in about fourteen days. The bacilli occurred "at the junction between the pyramidal and cortical portions of the kidneys" (*Zeitschrift fur klinische Medicin*, 1887).

Perhaps the criticism which may be more effectively made against Dr. Hopkins' claim to have discovered a new form of nephritis is that his case was one of general microbic infection, and that the kidneys were not the primary or chief centres of the morbific action.

News of the Week.

The First Execution by Electricity.

By Telegraph to the MEDICAL RECORD.

THE first execution by electricity took place at Auburn Prison, at 6.49 A.M., August 6, 1890. The criminal was William Kemmler, whose name has become so widely known as that of the first victim of the new method of killing, around which there has centred so much scientific discussion and so many legal technicalities. The means to the end of the enactment of the new law of electrical execution for the State of New York are so well known as to render repetition unnecessary. Suffice it to say, however, that the method was finally decided upon after numerous scientific experiments regarding the deadly forces of the alternating electrical current upon the lower animals, coupled with the demonstration of their rapid and painless action. After the taking, by the commission appointed by the legislature, of an almost exhaustless amount of testimony from electrical experts and others, the law abolishing hanging and substituting execution by electricity finally passed the legislature and received the approval of Governor Hill. It was the aim of all interested in the outcome of this novel method of killing to make "assurance doubly sure" as to the result, and it was accordingly agreed that a dynamo generating a voltage of from 1,000 to 2,000, and with a current alternating from 200 to 300 vibrations per second would certainly answer every purpose. Founded upon such recommendations the apparatus used in the execution of Kemmler was constructed. It consisted of a dynamo capable of generating an alternating current of 2,000 volts, with a death-chair, and suitable electrodes, the victim completing the circuit. The death-chair was made from heavy oak, with a high, straight, and slightly inclining back and broad arms. To the back of the chair was a sliding wooden arrangement, the upper portion of which was shaped like a figure **4**. The base or horizontal arm of this figure projected forward, from the end of which was suspended the head electrode. The latter resembled very much in shape, as it hung in position, a dinner-bell with an ordinary handle; the bell being the rubber cup and the handle constructed of wood, through the long axis of which the wire of the electrode passed. This wire terminated in a metallic disk, which, being covered with a sponge, was, by a spring arrangement and the sliding down of the figure **4**, brought in contact with the top of the head of the culprit. The other electrode was fastened to the lower portion of the back of the chair, and corresponded in position with that of the hollow of the sacrum. This disk of the electrode was constructed similar to the first, and arranged in such a way that it could be strapped against the surface of Kemmler's body. There were other straps to fasten the chest, trunk, arms, forearms, and legs to corresponding portions of the chair. The head was secured by a leather mask formed by a forehead and chin band, which was fastened to the back of the chair, leaving the nose, cheeks, and mouth exposed. The wire of the head electrode was suspended from the ceiling, while that of the other electrode passed along the floor, and, with the victim in position, completed the current. At one time during the discussion of the

best method of transmitting the currents it was proposed to send them through the upper part of the trunk only, by applying the head electrode as before indicated and immersing the hands in bowls of water connected with an electrode. It was argued, and with good reason, that the electro-motor force would thus be expended on all the vital centres and death be as instantaneous as by the other means. It was feared, however, that the possible struggles of the culprit might interrupt the current and thus cause the dreadful experiment to fail. Aside from this the ultimate effects would probably have been the same.

Twenty-six physicians and gentlemen witnessed the execution. Among those invited by the warden were Drs. Carlos F. McDonald, E. C. Spitzka, W. T. Jenkins, and George F. Shrady, of New York; Louis Balch and W. J. Nellis, of Albany; Henry A. Argue, of Corning; A. P. Southwick, C. M. Daniels, and George E. Fell, of Buffalo, and T. K. Smith, H. E. Allison, and Oliver A. Jenkins, of Auburn. The warden was also present. They were seated on chairs set in the form of a horseshoe, in the opening of which the death-chair, screwed to the floor and properly insulated, was situated. When everything was in readiness, Kemmler, dressed in ordinary clothes, was led into the room by the warden and introduced to the witnesses present. He was strangely calm under the circumstances, and after a few remarks in reference to his readiness to die, quietly removed his coat and adjusted his cravat, as if to get ready for any ordinary operation. With a forced assurance in his own mind that death would be instantaneous and absolutely painless he deliberately sat in the chair, crowded his bared back against the lower electrode, lent his assistance to the buckling of the confining straps, and even directed that the head electrode be firmly secured in position. While these preparations were in progress, as if appreciating his part in the tragical performance, he apologetically remarked to the spectators that he would do his best to act his part properly. With tender consideration on the part of the warden only two or three minutes were consumed in adjusting the appliances. Then came the time for the signal for turning the fatal switch. In an instant the victim was apparently driven into a shrinking, crouching, rigid mass, with the exposed features in a grin, and the muscles of the entire body in fixed and rigid spasm. He remained in this condition for seventeen seconds, when the current was interrupted and the muscles became relaxed with a momentary and quivering uncertainty. Then all was still and the patient was pronounced dead. Seventy-three seconds after the current was turned off a slight heaving of the chest was noticed, and this was immediately followed by slow, rhythmical, stertorous breathing. Although every sensation was abolished the forced breathing continued, and with each expiration a slight amount of mucus was bubbled through the closed lips. Notwithstanding the fact that directions were immediately given to turn on the current again, by some misunderstanding on the part of the one who ran the dynamo this was not done until two minutes had elapsed. Then the same phenomena were repeated, and the culprit was kept under the full power of the instrument—fourteen hundred volts—for two and one-quarter minutes, when all the unpleasant symptoms disappeared. As the result of this long-continued current the moisture in the sponge of the lower electrode became separated and resulted in the deep burning of the flesh at that point. As soon as the resulting smoke was discovered the circuit was at once interrupted. On examination of the body immediately after the interruption of the second current, Kemmler was declared dead by Drs. Carlos F. McDonald and E. C. Spitzka, the gentlemen who were appointed as the physicians by Warden Durston. The pulse had ceased to beat, the pupils were dilated, and upon the exposed portions of the face and the backs of the hands evidences of commencing capillary post-mortem changes were evident. Three or four minutes after the disconnection of the second current the eyes were examined again, when the corneæ were found to be depressed and the eyeballs flaccid on pressure. Kemmler was then left in the chair until the autopsy was held.

Auburn, August 6.—The autopsy was held three hours after death, under the supervision of Drs. Carlos F. MacDonald, E. C. Spitzka, and George F. Shrady, of New York, and performed by Dr. W. T. Jenkins, of New York, assisted by Dr. Clayton M. Daniels, of Buffalo, N. Y.

Dr. Shrady this evening gave out the following as the results of the autopsy so far, as information for public use: Body fairly well nourished. Rigor mortis marked, particularly in the muscles of the jaw, neck, and thorax, and gradually extending from above downward, involving the feet and legs last. The post-mortem hypostasis marked over lower portion of body and extending up as far as the anterior axillary line, also on the pendant surfaces of the upper and lower extremities. The upper extremities are partly flexed and rotated outward, the nails showing post-mortem lividity. There was a seminal discharge which on microscopic examination was found to contain a large number of dead spermatozoa. There was marked discoloration of the forehead about an inch in width, corresponding with the position of the strap, beginning at the hair line on the left side and extending to the hair line on the right side. A corresponding discoloration from the pressure of the chin-strap was also noted. There was an oval depression of the scalp upon the vertex, beginning at the anterior hair line and measuring four inches in its long and three and a half inches in its short diameter. Anterior to the posterior portion of the depression and in the immediate line there was a burn one and one-half inch in length and half an inch in width, superficial in character, slightly scorching the hair and crescentic in shape. On small of the back, corresponding to the level of the fourth sacral vertebra, below and second above, four and one-half inches in vertical diameter and four and one-half inches in transverse diameter, was a burn presenting four concentric zones, of which the outermost had a pale area, corresponding to that of the rubber cup of the electrode and one-fourth of an inch in diameter.

Succeeding this was a partial and complete vesication, partial below and complete above, about an inch in diameter above and one-third of an inch below.

Then follows a transition zone, which is in its upper third a complete eschar, black in appearance, and in its lower part shows desiccation and is of a greenish-brown color. An internal zone shows a number of vesicles, chiefly peripheral, and below the centre a black eschar,

half an inch in its vertical and five-eighths of an inch in its transverse diameter. Above is a tongue-shaped pale area with a lateral projection to the left of the median line, extending about two inches, and an upper projection in the dorsal furrow which is more sharply pointed and which on its periphery shows a reddened portion with here and there vesication. In addition the back showed a number of depressions produced by the folds of the shirt and suspenders, such as are commonly found in dead bodies lying on the back.

On incising the skin over the sternum the blood which escaped was unusually dark and fluid and remained so on exposure. There was no vermicular action of the intestine on exposure to the air or on irritation. The diaphragm extended from the fifth intercostal on the left and the fourth on the right. The blood from the cut surface of the liver was of a crimson-like color. Abdominal organs were normal in position and appearance. The muscles of the thorax were of the usual color. Tar-like spots were noticed on the posterior border of the lower lobe of the left lung. Over half of the lung floated when placed in water, showing a marked emphysematous condition. The bronchi were normal in appearance and contained mucus and air-bubbles. The right lung was adherent throughout to the diaphragm. In the middle lobe of this lung there were numerous well marked tar-like spots. The spleen was normal in size and appearance. The left kidney weighed three and one-half ounces and the right kidney three ounces; both were intensely congested. The stomach contained a pint of undigested food. The gall-bladder was distended with bile. The heart weighed five and three-fourths ounces, valves were healthy. Bladder contracted.

The scalp on being removed showed the vertex of the skull to be in a desiccated condition, corresponding with the contact of the electrode as previously noted, but of larger area, being four inches by four inches, the zone of the scalp being only two and a half by three inches, the long diameter being antero-posterior. On removal of the skull-cap the dura was normal in texture, somewhat dull in color, particularly over the area corresponding with the zone of contact. In the prerolandic region the meningeal vessels, measuring along the convexity antero-posteriorly four inches on the left side and three on the right, were filled with carbonized blood. On the internal aspect of the calvarium the meningeal vessels in the dura and their contents appeared to be black and carbonized. The carbonized vessels were so brittle that their ends were torn off with the calvarium and presented a broken, crummy appearance. This carbonization was limited in an abrupt manner. The other menin geal vessels contained blood of a crimson-like hue, corresponding to the outer burn previously described. In its narrowest portion was seen, a little posteriorly in the median line, a dark, discoloration sending out a right lateral prolongation three-fourths of an inch in the direction of the longitudinal sinus, and in width seven-eighths of an inch. Over the left hemisphere, one-third of an inch left of the median line, there was a deep carbonized spot corresponding with the carbonized portion of the calvarium. This charred spot corresponded to the dull-colored areas previously described. The pia and gyri themselves were of a pale buff color, the rest had the ordinary rosy injection of the ordinary cortex. While observing this anæmic area it was noticed that its blood-vessels began to fill. The pia and arachnoid on the convexity were perfectly normal. An interesting fact was observed on handling the pons and medulla, in that they were found to be warm. By a thermometer inserted in the fourth ventricle, the temperature was noted at 97° F. This corresponds with an area of temperature on the back of the neck which was noted as 99° F., two hours after death, and 97½° F., three hours post mortem. The smaller vessels of the pia were ectatic. Capillary hemorrhages were noted in the floor of the fourth ventricle, and the same condition in the third ventricle and the anterior portion of the lateral ventricle. The perivascular spaces appeared to be distended with serum and blood. The brain cortex in the area of contact was sensibly hardened to one-sixth of its depth, where there was a broken line of vascularity. The vessels over the corpus striatum showed enlargements in different parts of their ramifications. The pons was slightly softened. The burned integument of the back, on being removed, showed the spinal muscles underneath to be cooked, like "overdone beef," throughout their entire thickness. The spinal cord was removed entire, but showed no gross appearances of pathological condition. Portions of its structure, as well as those of brain-tissue, were preserved by members of the staff for purposes of hardening and microscopical examination. The blood taken immediately after death showed under the microscope a markedly granular condition, almost suggesting an electrolytic dissolution of the red corpuscles.

The French and the Berlin Congress.—It now appears that, in spite of hostile agitation, a very fair proportion of Frenchmen is attending the present International Congress at Berlin. The number of French doctors visiting Berlin is estimated at nearly two hundred. Regarding the true motive underlying the advocacy of French non-participation, a writer in the *Union Médicale* says, it was not the Virchow-Starck affair, which Dr. Huchard made the most of at the very time when the French press, both lay and medical, were uniting to bury all differences. The real reason, it is asserted, is the neglect which Germany showed to the Paris meetings of last year. At any rate it is comforting to find in the current issue of the *Journal de Médecine de Paris*, an earnest plea in behalf of French attendance at the Berlin Congress. To the question "*Devons-nous aller au Congrès de Berlin*," an emphatic yes is given as answer. One can go to Berlin without ceasing to be *bon français*, is a sentiment that does credit to the editor of the *Paris Médical*.

The Worst Form of Loneliness.—The doctor who has not yet attended a Medical Congress.

Legal's Urine Test in Tumors of the Liver.—At the Vienna Surgical Society Professor Nothnagel recently showed a patient with a hard tumor in the liver. He applied Legal's urine test, and found it perfectly accurate. Legal's test solution is a mixture of the nitro-prussiate of soda, to which a solution of potash is added. If aceton be present in the urine when this is added the urine takes a dark red color, which is intensified when acetic acid is added. This test is said to be alone sufficient to prove the presence of a melanotic tumor.

The Hydrophobia Scare.—Chicago is to have a new hospital for the inoculation of hydrophobic virus. Already the statistics are picking up in that vicinity. If the poor dog could only speak and smile, what would he say and do?

Dr. William Brodie, aged sixty-seven, one of the best-known physicians of Michigan, died at his home in Detroit. He held many prominent offices in medical circles and was highly esteemed.

Dr. W. G. Stevenson died at Poughkeepsie, N. Y. He was born in Sandusky, O., in 1843, and was graduated from the College of Physicians and Surgeons in New York in 1865. He was a member of the Board of Education.

Dr. R. C. Word, a prominent physician of Georgia, died July 20th. He occupied the position of Professor of Physiology in the Medical and Dental Departments of the Southern Medical College in Atlanta, and was for many years associate editor of the *Southern Medical Record.* He was graduated at the University of the City of New York in 1846.

Mr. Thomas Bryant, Vice-President of the Royal College of Surgeons, England, has been elected President for the ensuing year in place of Mr. Jonathan Hutchinson, whose term of office expires. Mr. Thomas Smith and Sir William MacCormac were elected Vice-Presidents.

Leprosy in Dutch Guiana.—According to a bishop of Dutch Guiana, leprosy prevails to a more serious extent in that colony than is generally supposed. Three of the Redemptionist fathers have been attacked by the disease, and one is now slowly dying of it at the leper station of Batavia.

A Congress of Microscopists will be held in Detroit on August 12th and three following days. The presidential address will deal with the influence of electricity on protoplasm, and among the papers announced is one by Professor Marshall D. Ewell, of Chicago, on some of the medico-legal questions involved in the Cronin case.

A Funny Health Officer.—The Michigan State Board of Health recently took Health Officer Davis, of Close Village, to task for failing to send in his weekly reports. His reply is unique. He says: "There has not been enough sickness here in the last two or three years to do much good." The physicians find time to go to Milwaukee on excursions, serve as jurors in justice courts, sit around on drygoods boxes, and beg tobacco, chew gum, and swap lies. A few sporadic cases of measles have existed, but they were treated mostly by old women, and no deaths occurred. There was an undertaker in the village, but he is now in the State prison. It is hoped and expected when green truck gets around, melons plenty, and cucumbers in abundance that something may revive business. If it does I will let you know."

The New Urban Hospital of the City of Berlin.—This new hospital has just been opened. Its erection cost three and a half million marks. There are in all five hundred and seventy beds, contained in eighty stately pavilions. The heating is by hot water or steam from central furnaces. The lighting is a peculiar feature; for the first time, as far as is known, no arrangements for any other light than the electric have been made. A double system has been laid on, so that in the failure of one the other would be equal to the occasion. An extensive arrangement of accumulators of the Tudor system stores up electrical energy for eleven consecutive hours. On arrest of the motion of the generators the whole system of lamps becomes automatically lighted, so that the entire edifice remains lighted through the night without any motion of the machinery. The electrical installation cost 160,000 marks.

The American Dermatological Association will hold its fourteenth annual meeting at Richfield Springs, N. Y., September 2d to 4th. Dr. Prince A. Morrow, of New York, is president.

The Doctor's Garden.—The Wiscasset *Liliputian*, of Maine, informs its readers that Dr. C. Peaslee is pulling down the fence between his premises and the cemetery. It goes on to say, "the view from his residence will be much improved after the stones in the cemetery are righted up." The view must be delightful at all times, especially to a physician. The removal of the fence, too, suggests the air of common ownership, the graveyard being, as it were, the doctor's garden. The doctor who can look upon a graveyard and enjoy an easy conscience is invaluable in any community.

Boycotting Irish Physicians and Surgeons.—The recent cases of the exclusion of Irish medical graduates from holding appointments in certain places in England, have caused the President and Council of the Irish College of Surgeons to issue a printed statement on the subject. It is a notorious fact that such institutions as the Liverpool Royal Infirmary and the Bristol General Hospital have decided that "no Irish need apply" for any appointment, and have decreed that fellows and members of the London colleges shall alone be eligible to hold office. The plea put forward for the exclusion of Irish medical men is that Irish examinations are inferior in standard and their degrees of less value than English ones. To show the utter absurdity of such a statement the Royal College of Surgeons in Ireland, through its Council, has sent out the document mentioned above. If there is one thing more than another which should at once set at rest this question, it is the fact that candidates who are "plucked" in Ireland in the main go either to London or Edinburgh and there obtain qualifications which the Irish College, through its examiners, had declared they were not entitled to. If the course of study and the examinations are taken a similar result is obtained. Irish students are required to undergo four annual examinations; three suffices for the English College of Surgeons. Ireland requires three courses of dissections, England only wants two. One course of lectures in anatomy is deemed sufficient in England, while in Ireland two are imperative. It would be not only a waste of time, but of space, to go through the entire list of study, which in each detail points *conclusively* to the greater severity of Irish examinations as compared with English. The tables of passes and rejections, as presented in the College statement, show that the rejections in Ireland are at least six per cent. higher than in the English College of Surgeons.—*The Hospital Gazette.*

The Medical Centre.—Philadelphia is again vaunting herself in one of the local papers as the Medical Centre of the United States. No one who lives in Philadelphia will doubt the fact.

The International Congress on Alcohol.—From the 3d to the 5th of September this Congress, the third of the series, will hold its sittings in Christiania, and the programme gives promise of highly interesting and, we trust, fruitful discussions. The report of the president of the permanent committee (Dr. Forel, of Zürich) will review the work achieved in lessening the evils of drunkenness between 1887 and 1890, after which papers will be read—1, On "The Means which have Proved most Effective in Norway for the Diminution of Alcoholism;" 2, on "The Results of the Gothenburg System;" 3, on "The Alcoholic Question in Relation to the Rearing of the Young;" 4, on "The Degeneration of Indigenous Tribes through the Spirit Trade;" and 5, on "Freely Diluted Alcoholic Beverages, or, in other words, Moderation as a Means of Combating Intemperance." Other papers on branches of the great drink question will be read by Dr. B. W. Richardson, Professor Böhmert, Dr. H. von Hebra, Dr. H. Kurella, and other distinguished promoters of the temperance cause. Many non-medical or lay friends of the same social reform will take part in the proceedings, the attractiveness of which will be materially enhanced by an exhibition of writings, illustrations, and various other objects bearing directly or remotely on alcoholism in all its ramifications. A similar exhibition was held at the last meeting of the Congress (at Zürich), and proved an excellent adjunct to the discussions.—*Lancet.*

The Annual Meeting of the American Climatological Association will be held in Denver, September 2d to 4th, and a successful gathering is expected. The Western Passenger Traffic Association has granted a one fare for round trip rate; tickets to be bought August 31st and September 1st, and good for return till September 25th, which is open to others as well as members. One-third of the time is expected to be given exclusively to the study of Colorado subjects, and after the three days' sessions the visiting physicians are to be given an opportunity personally to investigate the mountain resorts by a series of complimentary excursions.

Scarlet Fever is again very prevalent in London, and the weekly returns show a steady increase in the number of cases. Special measures have been ordered to be prepared for the prevention of its further extension.

A Pleasant Japanese Watering-place.—The watering-place of Kusatsu has a great reputation among the Japanese in the treatment of leprosy. M. Louis Bastide, who recently visited it, found three hundred lepers in residence there; they live in certain special hotels, in which every one, from the proprietor to the waiters, is a leper. Some of those who resided in Kusatsu were mere beggars, but others were persons of a better class, who took the waters diligently, hoping for a cure.

Professor Schmidt-Rimpler, of Marburg, has been appointed to the Professorship of Ophthalmology at Göttingen, vacated by Professor Leber, who has gone to Heidelberg. Professor von Hippel of Königsberg has declined the invitation to come to Göttingen.

Society Reports.

International Medical Congress.

TENTH SESSION.

Held at Berlin, Germany, August 4, 5, 6, 7, 8, *and* 9, 1890.

(Special Cable Report to the MEDICAL RECORD.)

FIRST DAY, MONDAY, AUGUST 4TH.

General Notes.—The first part of the Tenth International Medical Congress surpasses all preceding ones in its size, at least, though it is yet too early to say what rank it will take as a scientific gathering. Over seven thousand members are registered, the great majority of whom are from Germany, the Americans probably coming second in point of numbers. There are not a few Frenchmen also, though not as many as it was hoped there would be. The hotels are filled to overflowing, and numbers are lodged in private dwellings. The general meetings are held in the Circus Renz, the largest available building in Berlin, yet far too small to accommodate all the members of the Congress. The acoustic properties of the building are not very good, and speakers can with difficulty be heard by those seated at a distance. The hall is handsomely decorated, a heroic bust of Esculapius above the tribune being the most conspicuous object. The meetings of the Sections, of which there are twenty, are held in the beautiful halls of the Exposition building. This building is easy of access from most all parts of the city, and is surrounded by an extensive park, in which are several restaurants and cafés where the members can refresh themselves when wearied with scientific labors.

Opening of the Medico-scientific Exhibition.—Although the actual work of the Congress did not begin until Monday, there was quite a large gathering on Saturday morning in the Exposition building, to assist at the opening of the Medico-scientific Exhibition. DR. LASSAR delivered the address, in which he explained the object of the exposition, and craved indulgence for any shortcomings because of the limited time given to the Organizing Committee to perform their work. This was but a beginning, and should be judged as such, but the speaker hoped it would lead to great results in the future. On behalf of the Congress PROFESSOR VIRCHOW thanked the Committee for their labor, and, after three cheers had been given for the Emperor, he declared the Exposition open.

GEHEIMRATH KOEHLER, as the representative of the Government, followed with a short address, and then the military officials present were shown through the buildings, the members of the Congress following. The Exposition is very creditable and instructive. It is located in the permanent exposition buildings, where also most of the sections meet. In addition to the usual exhibit of surgical appliances and pharmaceutical preparations, there are shown anatomical, histological, and pathological specimens, models of field hospitals, conveyances for the wounded, methods of bacteriological investigation, and many other objects of interest to medical men.

Opening of the International Congress.—The first general meeting of the Congress was held in the Circus

Renz on Monday forenoon. It was called to order by the President of the Committee on Organization, PROFESSOR VIRCHOW, who delivered the Address of Welcome. He spoke of the difficulties encountered by the Committee in providing for so many guests, and hoped that their work would be judged leniently. He thanked the members for coming in such numbers, and extended to them a warm greeting. He said the Emperor regretted not being able to be in the city, but had given orders for the reception of guests. He then spoke at some length of sanitary undertakings in Berlin, and closed with a few words of hearty welcome. Secretary-General Lassar then made his report. MINISTER VON BOETTICHER, as the representative of the German Empire, followed with an address, in which he referred to the special interest taken by the Government in sanitary measures, and assistance rendered them in this work by the medical profession. MINISTER VON GOSSLER then welcomed the members on behalf of the Prussian State. Other addresses were delivered by Herr von Forckenbeck on behalf of the city of Berlin, and Dr. Graff, President of the German Medical Society. Addresses from the foreign members then followed. Surgeon-General Hamilton spoke for the United States; Sir James Paget, for England; Professor Bouchard, for France; Professor Bacelli, for Italy, his address being in Latin; Professor Czatary, for Austro-Hungary; Professor Aretaus, for Greece; and Professor Pashutin, for Russia. The names were then read of the honorary Presidents of the Congress.

PROFESSOR VIRCHOW was nominated and unanimously elected president of the Congress. A recess was then taken to enable the audience to breathe a little fresh air, for the day was warm and the atmosphere within the building disagreeably close.

The Present Position of Antiseptic Surgery.—The scientific work of the Congress was opened by Sir Joseph Lister, who delivered an address on "The Present Position of Antiseptic Surgery." He dwelt at some length upon the theories of immunity developed from results of bacteriological studies, referring especially to Metshnikoff's hypothesis that pathogenic micro-organisms are destroyed by certain cells called phagocytes. He then gave a review of the origin and development of antiseptic surgery, taking occasion to declare himself a firm upholder of antiseptic in contrast to aseptic methods, although the latter were not without their uses. He maintained, however, that strict cleanliness, as insisted upon by Lawson Tait, and the use of boiled water were really antiseptic measures. The speaker had modified in many ways his original methods, had wholly abandoned the spray, and said that he felt ashamed that he had tried, and advised others to try, to destroy the microbes in the air. He was a believer in the efficacy of sublimate solutions and used them in strengths ranging, according to circumstances, from one in five hundred to one in ten thousand. He had also used cyanides of zinc and of mercury, and recommended them as efficacious antiseptics. He then referred to special indications in the antiseptic treatment of thoracic fistulas, contused wounds, joint injuries, etc., and closed with the reaffirmation of his belief in the necessity of antiseptic as opposed to so-called aseptic surgery.

Bacteriology.—The second address was by DR. ROBERT KOCH, who had naturally selected for his subject "Bacteriology." The address aroused much interest because of the promise that the near future migh witness the development of a method for the prevention and cure of tuberculosis. The speaker reviewed recent progress in the science of bacteriology, and the results already achieved. The time had passed when the specific microbes of certain infectious diseases could be regarded as harmless or accidental parasites. Methods of culture and inoculation experiments left no room to doubt the causal relation of special micro-organisms to certain specific diseases. That this discovery had hitherto led to no striking therapeutic results argued nothing against bacteriological study. It had already given rise to many measures of undoubted utility, such as sterilization of milk, disinfection of morbid excretions, filtration of water, etc., and had furnished a sure method for diagnosis of certain diseases, such as tuberculosis and cholera. The fact that we had hitherto failed to discover the specific cause of rabies, pertussis, yellow fever, and other diseases, was no argument against bacteriological methods as at present employed. It was very possible that the causes of these diseases belonged to a different order of micro-organisms, and could not be discovered by our present methods of research. In favor of this view was the fact that the micro-organism of malaria was a plasmodium belonging to the protozoa, and not to the vegetable kingdom. The speaker believed we were just entering the second stage of bacteriology, where we should have to do with protozoa as disease-producing germs.

Immunity against Tuberculosis.—Referring again to the practical results of bacteriology, Koch said that it had hitherto furnished means only for the prevention of disease, but had not helped us to cure disease already established. He thought, however, we were on the eve of practical therapeutic developments based upon this science. It was not his custom to publish his investigations until they were completed, but he would make an exception this time. He had not only succeeded in conferring upon guinea-pigs, which are known to be peculiarly susceptible to tuberculosis, perfect immunity against that disease, but had also discovered means of arresting the growth and multiplication of tubercle bacilli after inoculation. If he should be equally successful in preventing and arresting tuberculosis in man, it was not too much to hope that means would be found for successfully combating other diseases. In closing his most interesting address, the speaker hoped that all nations of the earth here represented would meet on one common field, and advance to victorious combat against these smallest but most dangerous enemies of the human race.

At the conclusion of this address, PROFESSOR VIRCHOW congratulated the members on the auspicious inauguration of the Congress, and declared the first general meeting closed.

Clinics.—In the afternoon the various sections were organized, and several clinics were given in honor of the guests. Among the latter was one by PROFESSOR WOLFF, to the Orthopedic Section, and a surgical clinic by PROFESSOR VON BERGMANN.

In the evening there was a social gathering of members in Exhibition Park. There was also a dinner of about seventy-five covers given by the Committee of Organization at the Kaiserhof Hotel. Among the Americans

present were Minister Phelps, Drs. Jacobi, of New York, Wood, of Philadelphia, and Billings, of Washington.

Tuesday was devoted to Section work. Early in the morning there were a number of clinics given in honor of the Congress in Augusta Hospital and the new city hospital. In the evening a reception in the Rathhaus, by the city authorities. Only about three thousand tickets were issued, and these were given to the first applicants, so that many of the foreign members, who arrived on Sunday or Monday, failed to receive invitations. As it was, the halls were uncomfortably crowded. The decorations were lavish and artistically beautiful, the grand staircase being almost carpeted with flowers.

The Second General Meeting was held on Wednesday morning. The crowd was not so great as on the first day, and the session was not as protracted. The result was that the orators appointed for the occasion had a better audience, for on Monday many were exhausted by the heat and left during and before recess, so that when the time came for Professor Lister's address the hall was, comparatively speaking, almost deserted. The addresses on Wednesday were by Professors Bouchard, of Paris, Axel Key, of Stockholm, and Wood, of Philadelphia.

The Mechanism of Infection and Immunity was the title of PROFESSOR BOUCHARD'S address. After reviewing the processes by which the animal organism is enabled to destroy bacteria, namely, phagocytosis and the bactericidal state, he spoke of the means by which bacteria caused disease. Microbes act by their secretions; these paralyze the vaso-dilator centre in such a way that exudation and diapedesis are rendered impossible. After artificial injection of this secreted material, phenomena of inflammation, namely, vascular dilation, redness, swelling, and heat, cannot be excited even by application of croton-oil. Now these products which hinder production of local lesions, that is, which prevent diapedesis, render more rapid and more grave general infection, and even render the latter possible in animals which possess natural or acquired immunity. This action occurs immediately after injection but lasts only six or eight hours.

The Action of Vaccinal Material.—The speaker then dwelt upon the action of vaccinal material. This acts slowly upon nutrition and produces a bactericidal state which continues long after the elimination of the vaccine. This state becomes manifest about two days after inoculation and is very pronounced at the end of three or four days. He then took up the question of infection. If the inoculated microbe falls into a markedly bactericidal region it will not develop and there is no disease. If it falls in favorable soil there is immediate development of disease; if the region is moderately bactericidal there is local modification of the disease. As soon as the number of microbes becomes sufficiently great the secretory products act and febrile and toxic symptoms appear. When the bactericidal state does not exist phagocytosis alone can struggle on in behalf of the animal organism. But phagocytosis is often impeded because secretions of micro-organisms paralyze the vaso-motor centre and render diapedesis impossible. Bacteria therefore multiply and disease progresses, but meanwhile vaccinal matters have begun to modify nutrition, and the bactericidal state becomes established. Disease has reached its acme and must decrease. In bactericidal soil multiplication of bacteria ceases, the secretions diminish, especially those which impede diapedesis, then white globules emerge from the vessels and the microbes already weakened in consequence of the acquired bactericidal condition of the tissues are destroyed by phagocytosis.

Cure of the disease is the first manifestation of acquired immunity. This immunity left by the disease is due to persistence of the bactericidal condition. If, in a vaccinated person, the same microbe no longer produces general infection, but provokes only a local lesion, that is to say, diapedesis, and consequently phagocytosis, it shows that the virulent bacterium is attenuated in a bactericidal medium, and in consequence of this attenuation no longer secretes a substance capable of impeding diapedesis. Natural immunity cannot be attributed to the bactericidal state; it depends upon the greater resistance of the vaso-dilator centre to the action of the paralyzing matters which certain animal species possess. This natural immunity can be overpowered by introducing a very large dose of the material impeding diapedesis at the same time with pathogenic microbes.

The Development of Puberty and the Relation of the Same to Diseases of School Children.—PROFESSOR AXEL KEY'S address on this subject followed. His conclusions were based upon a large number of examinations as to the growth in height and weight of children during school age. It was found that marked arrest of growth occurred at the time of puberty. In winter the growth in height was most rapid, while in summer increase in weight was three times as rapid as in winter. This difference he attributed to the influence of the vacation period. School children are worked too hard, the hours of study are too long and encroach upon the time needed for sleep. Care should therefore be taken to lighten the labors of school children, especially just before and during puberty. In this way much chlorosis, habitual headache, scoliosis, etc., could be prevented.

These two addresses were very long, the weather warm, and the hall oppressively close, so PROFESSOR VIRCHOW announced the delivery of Dr. Wood's address postponed until the general meeting on Saturday.

In the afternoon Section meetings were held, as usual, in the Exposition buildings.

In the evening members of the various Sections met for dinner in different parts of the city.

The weather has been hot and damp, and the attendance at the general and Section meetings has consequently been less than it should have been.

Rome has been selected for the next meeting of the Congress.

A meeting of Americans was held on Tuesday to consider the advisability of inviting the Congress to Chicago in 1893, but it was wisely decided not to do so.

Permanganate of Potash Baths in Small-pox.—Dr. Galewouski, of Paris, reports that in the small-pox hospital at Brunn, in Austria, baths colored red with permanganate of potash are used for the treatment of small-pox. It is stated that after a short stay in the bath the temperature of the patient falls materially, his general health is improved, the pustules are resolved, and recovery sets in.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, April 24, 1890.

EGBERT H. GRANDIN, M.D., CHAIRMAN.

Laparotomy for Tubercular Peritonitis.—DR. CURRIER presented specimens from a case of diseased tubes and ovaries, and referred to one which brought up the question of laparotomy in tubercular peritonitis.

DR. JOSEPH PRICE, of Philadelphia, said he had operated in a number of cases of tubercular peritonitis, and all had done well except those in which drainage had proved impossible without injury to the viscera.

A Case of Kyphotic Pelvis.—DR. C. D. SCUDDER gave the history of the case, which was of interest in respect to treatment. The patient was a short, slight, deformed girl, aged twenty, unmarried, who had suffered from rickets until twelve years of age. The genital organs were normal. She seemed to be in the thirty-first or thirty-fourth week of pregnancy. The pelvis was contracted, the estimated measurement at the brim, anteroposteriorly, being about three inches, the transverse two and three-fourths. The question arose whether to bring on labor or wait till term and do Cæsarean section. The patient's condition was bad, and was likely to grow worse, so that it was decided to bring on labor, and should version fail, be prepared for Porro's operation. He succeeded, although with great difficulty, in introducing the hand into the vagina, the patient being under ether, and with two fingers in the uterus, skilfully aided by external manipulation made by Dr. Kelly, succeeded, after some time, in grasping a foot and performing version. The fœtus was then successfully extracted, and survived thirty hours. It weighed three pounds and thirteen ounces; the circumference of the head was thirteen inches, the occipito-mental diameter four and five-eighths. A complete right lateral laceration of the cervix was the only accident. The successful issue of the case showed what could be done under favorable conditions by conservative treatment.

The paper was discussed by Drs. Price, Hoffman, and Baldy, of Philadelphia, and J. D. Kelly, Hance, Dudley, Vonramdohr, the President, and author of the paper, of New York. Dr. Price referred to three cases recently sent to the hospital for the Porro operation or Cæsarean section, in which he succeeded, after trying labors, in delivering the women of living children. For his own comfort, he would prefer in similar cases to do Cæsarean section or the Porro operation; but he thought in many of the cases where Cæsarean section had been resorted to of late, a living child might have been brought into the world by the natural passages had premature labor been brought on about the eighth month. Dr. Hoffman had recently brought on labor in a case of male-pelvis at the eighth month, the patient having preferred this procedure to Cæsarean section, which had been suggested by another physician. She had once before given birth to a living child by the use of instruments. There was a woman in Philadelphia who had once given birth to a living child without the use of instruments, another time instruments were used and the child died. A third time she fell into the hands of an operator, and passed successfully through Cæsarean section. A fourth time she passed through a premature delivery. Cæsarean section, he said, had its place, but it was limited. Dr. Baldy also referred to some cases showing the success of nature's efforts where it had been supposed instruments or an operation would be necessary. Dr. Hance mentioned the case of a girl, aged thirteen, on whom it was expected to have to perform Cæsarean section, and they were surprised to see her delivered naturally, at the end of two hours, of a child weighing nearly seven pounds. Dr. Dudley thought Cæsarean section should not be instituted until labor had actually begun, and perhaps had continued several hours, for the reason that the child sometimes passed in a natural way where it was thought almost impossible. Yet he had had one case delivered with instruments, although with extensive cervical rupture, and two years afterward, last December, at a second labor, two hours of hard work with instruments brought forth another child, whose head was nearly twice the usual size. The woman did not rally, although there was no hemorrhage, and he was led to think rupture had taken place through the old scars into the peritoneal cavity. Dr. Vonramdohr cited cases showing error of judgment on the part of the physician, and difference in moulding qualities of the fœtal head. He had confined a woman four times. At her first pregnancy another physician did craniotomy. At the second, the speaker delivered her of a dead child, with forceps. He afterward delivered her of two living children prematurely, which died. The fifth time she allowed pregnancy to go to term, had a normal labor, and the child continued to live. He would, therefore, wait to the last moment consistent with the safety of the mother and child, and then do craniotomy, especially if the child were believed to be dead. The chairman said the discussion showed that obstetrics was full of surprises. Usually in kyphotic pelves one diameter was greatly diminished, others increased, and he thought the skilful obstetrician could safely conduct the child through if labor were brought on at about the eighth month, and this procedure was to be preferred to Cæsarean section. But the same rules did not apply to other varieties of deformity. He thought craniotomy would have to give place to Cæsarean section whenever the child was alive.

A Gynecological Table, Constructed entirely of Metal and Glass, was exhibited in model by Dr. Edebohls.

Salpingo-oöphorectomy and its Results was the title of a paper read by DR. H. J. BOLDT. (See p. 545, vol. 37.)

The discussion which followed was very prolonged, touching upon nearly every phase of salpingo-oöphorectomy, and was participated in by numerous gynecologists.

DR. JOSEPH PRICE, of Philadelphia, said, with regard to psychical manifestations, that in none of his cases had insanity followed the operation, although one had been mistakenly attributed to him at the Norristown Asylum. Altogether three cases had been reported from that institution. He spoke, however, of a "hospitalism," or chronic mental condition, from going the rounds of the hospitals and dispensaries, from which nothing could arouse these patients, an unsexing which he said was worse than the unsexing resulting from the loss of the ovaries. One cause of after-troubles was the stitching of cyst or pus sacs into the abdominal incision instead of removing them; another was adhesions, which at times seemed unavoidable. Post-operative inflammatory sequelæ should never occur. Pelvic abscess, vesico-vaginal fistula, mural abscess, indicated failure in execution; fecal fistula and ventral hernia should not occur. As to the kind of cases operated upon by him, he dismissed nearly all the "border-line cases," so called, or walking cases. He did not mean, however, to recommend the rejection of all of this kind, for sometimes he had been called, two or three years afterward, to operate when the pulse was 140 and the abdomen full of pus (rupture of a pyosalpinx having taken place). The speaker went on to state that refusal to operate in cases which were instead treated by electricity or other local measures resulted sometimes in the development of tuberculosis of the lungs, etc. He showed some drawings in proof that strictures took place in the tubes, in some cases of salpingitis, which could not be overcome by electricity or other measures intended to favor absorption of the tubal contents or their escape through the uterus. Puerperal pyosalpinx was very interesting, he having operated during the past winter in eight cases, as a life-saving measure. His paper was mostly an argument against too great conservatism.

DR. HOWARD KELLY, of Baltimore, had had insanity follow gynecological operations in three cases. In one a double pneumonia developed after the operation, and

prolonged insanity, but this patient had before been insane. One worried because it was reported she had been in the hospital to be relieved of a child, instead of a tumor. The other was a recent case, and likely to recover. Since 1886 he had performed oöphorectomy in ninety-six cases. In speaking of ultimate results, he omitted all cases not heard from six months after the operation, but he inferred they were relieved, otherwise the patients would have returned to make complaint. Eight of the operations were for fibroids. The patients were symptomatically relieved. Twenty-five were heard from who were operated upon for simple salpingitis and oöphoritis. One, operated on in 1886, required removal of the other tube and ovary in 1888; slow healing fistula; patient improved. Three had fecal fistulæ, one a fistula of the left ureter, all healed. Two patients got well, but had uterine hemorrhages after a year, and were found to have a mass at the cornua uteri, shown, by operation in one, to be an encysted ligature. Two others had encysted masses close to the uterus. One discharged pus through a scar, another a ligature through the vagina after incision; two patients had hernia; two suffered from the same severe headaches which they had before the operation. He knew of no case, however, not symptomatically improved —speaking strictly of local conditions, and not of other ailments which they may have had before the operation. Classifying separately the cases in which the inflamed tubes and ovaries were bound down by adhesions of pelvic peritonitis, there were thirty-three, thirteen of which were well, seventeen improved; one had been improved, but was troubled much from frequent desire to urinate; another patient had died, cause unknown to him; one, operated upon last year, not improved. Three were operated upon twice. His opinion of these cases was that the results justified the operation. Out of twenty-five cases of lesser disease of the ovaries requiring their removal, with that of the tubes, he knew eight to be well, most of the others to be more or less improved; one had hystero-epilepsy.

Thus, statistics of this operation went to show, 1, that a small percentage of the patients were restored to perfect health within a few weeks; 2, that a larger number experienced only a certain amount of improvement, the operation, however, forming a necessary stepping-stone on the way to comparative health; 3, that a few cases were subjectively not better after the operation than before, although seriously diseased structures may have been removed.

It was at once evident from this that abdominal surgery stood upon the same plane as general surgery, and that successful results were not often absolutely good, but were, finally, relatively good. According to the class of cases the operation was necessary or elective.

Dr. W. T. Lusk considered the results of treatment of pelvic cases at present, compared with results obtained in the past, when they were regarded as pelvic cellulitis. Under old methods patients got along usually pretty well, but there was a small proportion which ended sadly—pus discharging above Poupart's ligament into the rectum, into the folds of the broad ligament, vagina, or bladder. When drained, cicatrices might form and give the patient much trouble afterward. Sometimes sudden death took place. If it was possible always to differentiate these cases from others in which recovery took place after local treatment, they, of course, should be operated upon. This, however, was not always possible, and he had often found, especially in young women, that removal of the tubes and ovaries resulted in a mental condition which showed that it was extremely important, if possible, to preserve these organs. He was not speaking of pain and suffering; many were relieved of these; but he was not absolutely certain that many of them were the same beings they had been before. They seemed to constitute a class in the community by themselves. They knew they were incapable of bearing children like other women, and suffered from mental depression. He therefore believed the conservative work which Dr. Polk was doing, trying to save the tubes and ovaries while treating them surgically in certain diseased conditions, was in the right direction.

Dr. W. M. Polk said his results from salpingo-oöphorectomy had been good, but he operated chiefly for gross lesions, or well-defined salpingitis and oöphoritis, usually shown by extensive purulent destruction. At the same time, he had not been convinced that many of these patients, and those ordinarily operated upon, would not have gotten well without operative interference, and the question had come forcibly to his mind whether, after all, a woman had not a great deal more to expect of a surgeon than mere relief from pain, or even from danger to life. Like Dr. Lusk, he had found women, at least those under thirty years of age, so often suffer from mental depression and a change of mind when deprived of organs which made them different from their sisters, that he had been led to try measures for their relief without unsexing them. These measures consisted in draining the tubes and excising cysts from the ovaries, which he had not then time to describe in detail. There was no question in his mind but what salpingo-oöphorectomy had been performed too often, for the reason that we had been unable to differentiate cases necessitating the operation from those which did not.

Dr. H. C. Coe referred to a paper, recently read by him, on the ultimate results of salpingo-oöphorectomy, and spoke especially of pain resulting from adhesions after such operations, which, he said, could not be avoided, at least by present known means. Thus many patients suffered as much after as before the operation.

Dr. J. R. Nilsen had found, out of considerable dispensary material, only thirty-six cases calling for salpingo-oöphorectomy, and in none of these had he had occasion to regret doing the operation. In two it was performed for insanity. One patient improved much, but here insanity had been brought about by habitual masturbation since childhood. The more marked the lesions found, the greater had been the improvement after operation; the severer the symptoms coincident with slight lesions, the less the improvement. Where there had been pain on sexual intercourse, improvement followed the operation. Patients not improved were likely to go to another surgeon, and he had seen a number who had been operated upon by others.

Dr. A. P. Dudley distinguished between continuance of pains of the kind existing before the operation for which the patient sought relief, and pains of a different kind after the operation. After the operation hot flashes, and the taking on of fat were common. Other pains, he thought, were due almost invariably to the formation of adhesions, and it was important, in view of this fact, to use a ligature which would be absorbed.

Dr. Goelet said he had made the statement in the Academy that the ultimate results of salpingo-oöphorectomy were not entirely satisfactory in more than half the cases, and it passed without question. This showed the extreme necessity for a thorough trial of other measures first, including electricity.

Dr. Baldy, of Philadelphia, had never seen a case of insanity following the operation, and thought the hot flashes, taking on of fat, and other changes, were only such as occurred at the menopause taking place at the usual period. Speaking of local measures, he referred to electricity as a humbug.

The Chairman said he had been confirmed in the view, by the discussion to-night, that in catarrhal salpingitis, small cysts of the ovaries, and conditions aside from pyosalpinx and larger tumors of the ovaries, removal of these organs was not justifiable. A symptomatic cure could be effected through local applications, galvanism, etc., and no more, if as much, could be said of salpingo-oöphorectomy.

Kansas City Academy of Medicine.—There is to be such an association in Kansas City, Mo.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-sixth Annual Meeting, held at Hotel Kaaterskill, Catskill Mountains, N. Y., July 16 and 17, 1890.

(Continued from p. 106.)

The Winking Test, a paper by DR. CHARLES E. RIDER, of Rochester. The object of the paper was to point out the relation that exists between the ability to close one eye independently of the other and the acuteness of vision. The attention of the writer was directed to this relation by the fact which he had freqnently noted, that such persons as surveyors, sportsmen, and others who use one eye for sighting objects, as a rule, close the poorer eye. Noting this, he was led to make a study of a series of cases numbering three hundred. The results obtained were as follows. The term isopia was suggested to indicate those having equal vision in the two eyes, and anisopia to indicate those having unequal vision.

Three hundred cases.			Male.	Female.
Cannot wink			1	30
Isopia.	Wink equal		30	33
	Wink unequal		4	27
Anisopia.	Wink equal		17	12
	Wink.	Better eye	4	12
		Poorer eye	64	66
			120	180

Of anisopic males who wink unequally, ninety-four per cent. wink the poorer eye, and of females, eighty-four and a half per cent. wink the poorer eye.

The practical applications of this test were referred to, and its availability in certain medico-legal cases mentioned.

New Tests for Binocular Vision, by DR. J. A. LIPPINCOTT, of Pittsburg. The tests suggested are the outcome of some observations and experiments, the results of which were published in *Knapp's Archives* for March, 1889, under the title of "Binocular Metamorphopsia Produced by Correcting Glasses." In practice, a convex cylindrical lens of 2 or 2.5 dioptrics, axis vertical, is held before one eye and the patient is asked which side of a card, ten or twelve inches square, held at the reading distance, appears the higher. The question is repeated with the axis of the cylinder horizontal. Then a concave cylinder is substituted for the convex cylinder, etc. The principal advantages which may be claimed for these tests, which are in fact stereoscopic tests without a stereoscope, are their variety and simplicity; and, moreover, the patient can be more closely watched when under observation than if his eyes are hid behind the eye-pieces of the stereoscope.

Can Hypermetropia be Healthfully Outgrown, by DR. B. ALEXANDER RANDALL. The writer claimed that the investigations showing the predominance of hypermetropia and the rarity of emmetropia, had not been properly accepted. The assumption of the prevalence of emmetropia has little basis, and the claim that the hypermetropia, which preponderates in infancy, is really less in childhood and has passed away at maturity, is in conflict with the best attested facts. Even the decrease of the grade of defect from infancy onward is slight, if, indeed, actual. He cited the results of all the investigations, giving data as to the relation of age to refraction. These showed a very slight decrease in the grade of hypermetropia, a decrease which is really surprisingly small in view of the large amount of pathological tendency toward myopia which has been observed. The author, therefore, held that all tendency toward emmetropia and myopia was pathological, not physiological.

Treatment of Muscular Asthenopia and its Results, by DR. HENRY D. NOYES, of New York. The paper was a statistical one, from which certain deductions were drawn. It was based upon a study of one hundred consecutive cases of muscular asthenopia in which prisms were employed. The cases had all been under observation sufficiently long to render the results worthy of study. Coexisting errors of refraction were found in certain cases, but the influence of such errors in the causation of the symptoms was excluded. Among the cases reported there were sixty males and forty females. The occupation of three-fourths of the cases was such as to demand persistent eye-strain. The majority of the patients were in good health, less than forty per cent. being in a feeble condition. The symptoms noted were ocular and general. Among the former were pain, blurring and unsteadiness of print, inability to look at moving objects, inability to look fixedly at any object, difficulty from seeing the nose, photophobia, unsteadiness of the globe, spasm of the accommodation, and conjunctivitis. Among the general symptoms found were headache, which often presented the singular feature of occurring on first waking, and increasing during the day, vertigo, nausea, insomnia, melancholia, pain in remote parts, tenderness over the orbital nerve, and nasal catarrh.

A study of refraction showed emmetropia in 47, hypermetropia in 25, myopia in none, astigmatism in 27, hypermetropic astigmatism in 21, myopic astigmatism in 4, mixed astigmatism in 2, and antimetropia in 1.

The muscles affected were noted as follows: weakness of the externi, 92; weakness of the interni, 4; general weakness of all the muscles, 1. In five cases there was in addition a vertical error. It is to be observed that the proportion of cases of weakness of the externi is not so great as would seem from this report. The proportion is probably about seventy-five per cent.

In the treatment of these cases attention was first paid to the indications presented by the condition of the general health. Many patients had been subjected to general and local treatment without relief. In some cases the use of prisms was at first tentative. In more than half the cases headache was a prominent symptom. It was in most instances relieved by the use of prisms. In some it was lessened, and in a few it was not benefited at all. In the larger number of cases prisms were worn constantly. The final results were: complete relief in 74 cases, moderate relief in 6, no relief in 13, temporary relief in 6.

The report of the Committee on Blindness was then called for and read by the Chairman, DR. LUCIEN HOWE, of Buffalo. The study made by the committee showed that about twenty per cent. of the cases of blindness were due to ophthalmia neonatorum and purulent ophthalmia, and suggested certain means of prevention in the way of legal enactments.

Legislation for the Prevention of Blindness.—DR. HOWE read a paper on this subject. As nearly one-fifth of all the blind in the various asylums are there because of ophthalmia neonatorum, and as nearly all these cases could be cured if seen in the very first stages of the disease, therefore the writer urged the necessity of requiring nurses to report promptly every such case to some proper medical officer. In other countries stringent regulations have been adopted in this respect concerning the duty of midwives, and it was deemed in every way desirable to obtain, as far as possible, here also the enactment of laws similar to that recently passed by the Legislature of New York. This is as follows:

Section 1. Should any midwife or nurse having charge of an infant in this State notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse so having charge of such infant to report the fact in writing, within six hours, to the health officer or some legally qualified practitioner of medicine of the city, town, or district in which the parents of the infant reside.

Section 2. Any failure to comply with the provisions of this act shall be punishable by a fine not to exceed one hundred dollars, or imprisonment not to exceed six months, or both.

Section 3. This act shall take effect on the first of September, 1890.

Purulent Ophthalmia, by Dr. J. A. Andrews, of New York.—It has been claimed that the gonococcus was the cause of gonorrhœa, and that purulent ophthalmia was due to the same cause. The writer had made a number of examinations to see if the gonococcus was always present in these two affections. He had found the gonococcus in all cases of acute urethral gonorrhœa. In 144 cases of chronic urethral gonorrhœa, he had found it in 108 cases. In the purulent ophthalmia of adults the gonococcus was found in all cases. In the purulent ophthalmia of the new-born, it was found in all cases, 122 in number. In the purulent ophthalmia of infants between the ages of two and three months, it was found in 3 cases out of 9 examined. This makes 364 cases examined, with the discovery of the gonococcus in 322. In nearly all cases the staphylococcus pyogenes aureus was also present.

In the treatment of purulent ophthalmia the uninterrupted application of cold, washing with a saturated solution of boric acid, and the use of a solution of nitrate of silver, not exceeding two per cent., was urged. The solution of nitrate of silver is to be applied once or oftener during the day, according to the indications. If the discharge is not profuse, once a day is sufficient. If the discharge and swelling increase, the application may be made more frequently. Nitrate of silver is not well borne when there is little inflammation. The writer had found experimentally that a two per cent. solution of nitrate of silver destroyed the infective properties of the pus in from six to ten seconds.

Cyst-like Bodies of the Conjunctiva.—Dr. Andrews also exhibited a drawing of cyst-like bodies of the conjunctiva. These occurred in a child five years of age, whose mother and brother had had trachoma. The child itself had no affection of the cornea or trouble with the eye. The microscope showed that they consisted of hypertrophied conjunctival tissue.

A Form of Xerosis, by Dr. Charles W. Kollock, of Charleston. The author described a form of disease commonly seen among weak and scrofulous colored children, which differed from xerosis, as commonly seen, in that the conjunctiva is never contracted. The cornea, although more or less affected, is never destroyed, and under proper treatment recovery takes place.

Two Cases of Glaucoma were reported by Dr. Kollock, presenting certain interesting features. In one case, fifty years of age, iridectomy was performed, but the operation was followed by increased tension lasting two days. A four-grain solution of eserine was then instilled every hour. Under this the tension rapidly fell to normal.

A Case of Embolism of the Upper Branch of the Retinal Artery, with Normal Vision, was reported by Dr. W. F. Mittendorf, of New York, in which, owing to the peculiar anatomical arrangement, the macula lutea was supplied by the lower branch of the retinal artery. In the lower part of the field vision was absent, but in the remaining parts of the field it was normal. The treatment consisted of pressure, massage, and digitalis. Vision is now returning in the lower portion of the field.

A Case of Recurrent Irido-choroido Retinitis, by Dr. Samuel Theobald, of Baltimore. Ida R——, aged twenty-five, was seen July 8, 1889. Her general condition was fairly good. There was no evidence of congenital or acquired syphilis. She was suffering from recurrent attacks of inflammation in the left eye, which she said had begun two years before, and had destroyed the sight of that eye six weeks before coming to the hospital. The eye had evidently been the seat of severe irido-choroido retinitis; the right eye showed no signs of disease. Enucleation of the left eye was strongly urged. This was declined. She was put on small doses of iodide of potassium, with instillation of atropia to the affected eye.

December 6th, she again came to the hospital, having had an attack of inflammation in the right eye three weeks before. The eye was somewhat improved. V = $\frac{15}{200}$. The left eye was at once enucleated, and atropia applied to the right eye. The next day the ophthalmoscope showed that in the right eye there had been a mild attack of iritis, and slight inflammatory changes could be seen in the retina. Iodide of potassium and biniodide of mercury were ordered, and the eye slowly improved.

December 23d, V = $\frac{15}{70}$.

January 3, 1890, another attack of inflammation suddenly appeared without apparent cause, V = $\frac{7}{200}$. The iodide was increased to five grains every three hours, and a large blister applied to the nape of the neck.

January 8th, vision had improved to $\frac{15}{200}$, but there was evidence of commencing iritis. The iodide was now substituted by hydrarg. biniodide, grain $\frac{1}{16}$, three times a day, and application of atropia to the eye. The eye steadily improved, and by January 28th V = $\frac{15}{200}$.

February 11th, the inflammation recurred. By March 10th this attack had been recovered from. Another relapse occurred March 28th. As the attacks seemed to recur with a certain degree of regularity, quinia was tried. Under this there was improvement.

May 28th, there was a most severe attack.

June 13th, tension for the first time was found above normal. The condition of the eye steadily grew worse, and June 24th, iridectomy was decided upon as a last resort. It was found impossible to grasp the iris with forceps, and as a result the intended iridectomy was converted into a simple sclerotomy. The effect of the operation was not satisfactory.

January 7th, she left hospital, suffering no pain, but the vitreous was as cloudy as before, and it was impossible to determine that there was even light perception.

Syphilis could be almost certainly excluded in this case. The most probable explanation is that the inflammation was through the medium of the sympathetic or trophic nerves, and was dependent upon pathologic changes in the ganglion centres which have to do with the nutrition of the eye.

A Contribution to Ocular Tumors, by Dr. W. H. Carmalt, of New Haven. Four cases of ocular tumors were reported, two of sarcoma of the conjunctiva, and two of glioma. One of the latter was a case of double glioma in an infant a year and a half old. Both eyes were enucleated, and so far there has been no return, a period of one year. In the second case the condition was not diagnosed, as the lens was cataractous, and nothing could be seen. Later on there was great pain, and the eye became disorganized, and was removed. A year later the child again appeared with the orbit filled with a neoplasm. The condition was then recognized. The growth was thoroughly removed and the parts cauterized with chloride of zinc. Five months later, just as healing was about completed, indications of cerebral trouble appeared, and in about ten days the child died. At the autopsy a tumor was found occupying the anterior portion of the brain. A second growth was found in the cerebellum, on the right side.

A Case of Orbital Cellulitis was reported by Dr. R. J. McKay, of Wilmington, Del.

Progressive Astigmatism, by Dr. Edward Jackson, of Philadelphia. The author reported seventeen cases in which the increase of the astigmatism in hyperopic eyes had made needful a change of the correcting lenses. Such an increase seems to occur in about two per cent. of all cases. It may be due to chronic congestion of the eye from eye-strain, resembling progressive myopia, or to a congenital tendency of the eye to develop thus asymmetrically. The latter mode of origin was pointed to by the blood relationship of several similar cases. Bearing these cases in mind, the surgeon could not promise that the astigmatism of an eye would remain constant, or assume that a colleague had been mistaken, simply because lenses previously ordered by him did not now suit the case.

Three Noteworthy Cases of Ametropia, by DR. SAMUEL THEOBALD, of Baltimore. The noteworthy feature in these three cases was the existence in each of so much better near vision than the age and refractive condition of the patient appeared to warrant. In two of them (Case I. and III.), it seemed as though the lids were used (as they can be by narrowing the palpebral aperture and altering the corneal curve) to render the retinal image more distinct. In one case (Case II.) it was noted that the pupils were exceedingly small. In Case III. it is noted that the pupils were not unusually small. The detailed histories of the three cases were then given.

CASE I.—Male, aged fifty, suffering with asthenopia, headache, etc. Had never worn glasses for distant vision, but for near vision he used + $\frac{1}{30}$ s.; with this he read Jaeger 1 at eight inches. The ciliary muscle was active. It was found that in the right eye there was H. $\frac{1}{9}$, and in the left H. $\frac{1}{9}$, with As. $\frac{1}{12}$. With this correction vision, which without glasses was only $\frac{20}{c}$ (?), was brought up to $\frac{20}{xx}$ —.

CASE II.—Dr. T——, aged fifty nine, suffered with asthenopia and hyperæmia of lids and conjunctivæ. The pupils were exceptionally small. For near vision he used + $\frac{1}{18}$ s., reading Jaeger No. 1 with the left eye, and Jaeger No. 2 with right eye. He was found to have in the R. eye H. $\frac{1}{16}$ ($V = \frac{20}{xx}$ +), and in the L. eye H. $\frac{1}{20}$ ($V = \frac{20}{xxx}$). For near vision the best results were obtained with + $\frac{1}{9}$ s. for R. eye, and + $\frac{1}{10}$ s. for L. eye.

CASE III.—Mrs. R——, aged fifty-four, never wore glasses, but had been able to read the small type of a newspaper. Her manifest error of refraction, as corrected, was R. eye + 6 D cyl. ax. 70°; L. eye + 4.25 D cyl. ax. 110°; and in near vision the addition of 1.50 D spher. to these cylinders gave the most satisfactory effect.

An Analysis of the Ocular Symptoms Found in the Third Stage of General Paralysis of the Insane, by DR. CHARLES A. OLIVER, of Philadelphia. In an analysis of some of the ocular symptoms in this disease, the author, after making thirty-three special observations of the motor, sensory, and purely local conditions, arrives at the following summary and conclusions:

1. The oculo-motor symptoms of the third stage of general paralysis of the insane—which consist in varying though marked degrees of loss and enfeeblement of iris response to light stimulus, accommodative effort, and converging power; lessening of ciliary muscle tone and action; weakening and inefficiency of the extra-ocular muscle motion—all show paretic and paralytic disturbances connected with the oculo-motor apparatus itself, all of greater amount and of more serious consequences than those seen in the same apparatus during the second stage of the disease.

2. The sensory changes of the third stage of general paralysis of the insane, which, though similar to those found in the second stage of the disorder, are so pronounced as to show a semi atrophic condition of the optic nerve head, and a marked reduction in amount of both optic nerve and retinal circulations, with consequent lessening of centric and excentric vision for both form and color, all indicate a degenerate condition of the sensory portion of the ocular apparatus, with impairment of sensory nerve action.

3. The peculiar local changes seen in these cases, which consist in conditions of the choroid and retina indicative of more pronounced local disturbance and irritation of these tunics than those found in the second stage of the disease, all represent the result of greater wear and tear given to a more delicate and more greatly weakened organ.

4. Both the motor symptoms and the sensory changes, as thus described in the advanced or third stage of general paralysis of the insane, furnish not only evidence of local disturbance of a more pronounced type than those found in the second stage of the disorder, but plainly show themselves as one of the many peripheral expressions of fast-approaching degeneration and dissolution of nerve-elements, most probably connected with related cortex disintegration and death.

An Elementary Discussion of some Cases of Tipped Spectacle Glasses.—DR. JOHN GREEN, of St. Louis, read a paper on this subject.

A New Operation for Symblepheron was described by DR. GEORGE C. HARLAN, of Philadelphia. In this case the lower portion of the lid was adherent to the eyeball as the result of the inflammation following an injury from molten metal. The lid was first dissected from the eyeball and the skin cut through, except at the attachment at each end. A flap of skin of sufficient size was then dissected below and turned up, so that the fresh surface was applied to the lid and the skin surface took the place of the conjunctiva. The result had been very satisfactory.

Cyst of the Iris Following a Penetrating Wound at the Corneal Margin which Caused Sympathetic Neuro-retinitis, by DRS. S. D. RISLEY and B. ALEXANDER RANDALL, of Philadelphia. A boy, aged ten, was struck on December 12, 1882, by an air-gun dart in the left eye which penetrated to the lens, and its withdrawal was followed by prolapse of the iris. This being irreducible, was drawn out and excised, and healing resulted with a slightly cystoid scar. The right eye had been weak and watering, and on January 22d showed distinct neuro-retinitis, and the vision quickly fell from $\frac{20}{xxv}$ to $\frac{20}{xl}$. Under alteratives and atropine he improved until, with + 2, vision equalled $\frac{20}{xxx}$ + on March 17th, and $\frac{20}{xx}$ on April 18th. Two months later there was a sudden attack of blindness with an epileptoid seizure. A year later vision with the right eye was $\frac{20}{xx}$ and with the left fingers at two feet. In March, 1890, he returned with the left eye red and watery, and with a cyst of the lower part of the iris. Vision nil. Tension slightly diminished. Enucleation was advised. After a delay of two months, during which time the cyst increased in size and vision declined in the right, the eye was enucleated. The microscopic examination has not yet been completed, but there is no sarcoma in the vitreous chamber.

Thrombosis of the Arteria Centralis; Central Vision Unaffected, by DR. O. F. WADSWORTH, of Boston. A young woman, aged twenty-four, had sudden diminution of vision in the left eye. The field was much contracted, but central vision was unaffected. Examination showed plugging of the central artery. The circulation on the macular region was, however, maintained by an anomalous vessel, a retino-ciliary artery.

Dr. F. M. WILSON, of Bridgeport, Conn., presented three specimens of "Filari Ocula Humani."

DR. GEORGE C. HARLAN reported a case of "Temporary Pulsation of the Retinal Arteries Following the Application of Homatropine."

Dr. Harlan also exhibited a modification of the "Noyes Ophthalmoscope."

DR. B. ALEXANDER RANDALL moved that the Society express its approval of the method of nomenclature of prisms suggested by Dr. W. S. Dennett. This was adopted.

The following officers were elected: *President*, Dr. Hasket Derby, of New York; *Vice-President*, Dr. G. C. Harlan, of Philadelphia; *Secretary and Treasurer*, Dr. S. B. St. John, of Hartford, Conn.; *Corresponding Secretary*, Dr. J. S. Prout, of Brooklyn.

The following were elected to membership: Dr. A. E. Ewing, of St. Louis, Mo.; Dr. Neil J. Hepburn, of New York; Dr. Charles M. Culver, of Albany, N. Y.; Dr. Richmond Lennox, of Brooklyn; Dr. Frank W. Ringl, of New York.

The Society then adjourned to meet with the Congress of American Physicians and Surgeons, September, 1891.

The Berlin Poliklinik.—The new University Poliklinik of Orthopœdic Surgery was recently opened at Berlin. Dr. Julius Wolff has been appointed chief surgeon to the institution.

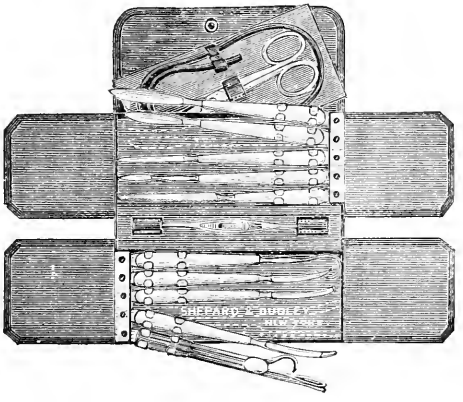
New Instruments.

A NEW ASEPTIC POCKET-CASE.

By WILLIAM R. LEONARD, M.D.,

NEW YORK.

DURING the last two years a number of articles have appeared in the MEDICAL RECORD with reference to aseptic pocket-cases. Some of the gentlemen have called special attention to the case itself, while others dwelt more particularly upon the instruments, many of which to my mind are mere toys, as the deviser endeavors to economize space by making the instruments too small for practical use. Then, again, the cases are faulty in construction, lined with velvet. The instruments are placed under loops which give no security to the knives, as one is apt to cut the loop with the blade while pulling out the knife, or pushing it through the distal end by undue force. The sides of the case are not protected, therefore all the instruments are liable to be injured. Even the metal case is objectionable. While carried on the person the slightest motion of the body makes the instruments rattle, which is disagreeable to hear; besides, the noise attracts attention to one's self, which is not pleasant to contemplate. This rattling is apt to injure the instruments by scratching the handles and gapping the blades, making them useless when most needed.



The case here presented is peculiar in construction, the arrangement being wholly original and differing from anything in the pocket-case line ever offered to the profession up to this time. This pocket-case is constructed with a metal plate each side, covered with alligator leather outside, and lined with leather inside that can be sponged off if necessary. These plates prevent the instruments from injury or protruding through the case; also for the purpose of securing clamps, sockets or loops of metal, and either pivoted or hinged. By this construction the clamps or sockets can be moved either laterally or at right angles to the longitudinal axis of the side-plates, as shown in the cut above; the said clamps or sockets being adopted to secure perfectly the handles of the several instruments, and if desired adjusted laterally, as shown by the dotted lines, whereby any instrument may be conveniently and expeditiously extracted or replaced without the fingers coming in contact with the blade. The clamps or sockets are so adjusted to the side-plates that they cannot slide one over the other, therefore making it impossible for the knives to come in contact one with the other; and it will be further observed that the metal side-plates effectually keep the case in shape, being perfectly flat when closed with its contents. It measures ⅝ inch thick, 2½ inches wide, and 5½ inches long.

The instruments in this case are all metal, and so made that aseptic material cannot find lodgement. They can be boiled or soaked in an antiseptic solution without the slightest injury. The blades and handles being one continuous piece, and full minor size, can be more readily held, easier cleansed, and much more convenient than the old style of pocket instrument made on the plan of a penknife, or even the recent turn-arm and slip-catch, so called aseptic for the purpose of catching the unwary. These latter instruments (old style) cannot be boiled or left in antiseptic solution without injury and permanent damage. The following is the list of instruments in the above case: 2 scalpels, medium and small; 1 tenotome; 1 finger-knife; 1 metacarpal saw; 1 tenaculum; 1 curved sharp-pointed bistoury; 1 curved blunt-pointed bistoury; 1 curved fistula bistoury; 1 director and artery needle; 1 exploring needle; 1 pair silver probes; 1 thumb artery and needle forceps, combined; 1 pair straight scissors; 1 silk catheter, needles, silk and silver wire.

The above case is made and for sale by Shepard & Dudley, New York.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 27 to August 2, 1890.

PRICE, CURTIS E., Captain and Assistant Surgeon. With the approval of the Acting Secretary of War, granted leave of absence for ten days. S. O. 175, A. G. O., Washington, D. C., July 29, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 2, 1890.

BLACKWOOD, N. J., Assistant Surgeon. Ordered to duty in the Bureau of Medicine and Surgery.

WALES, P. S., Medical Director. Ordered to duty in charge of the Museum of Hygiene.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 2, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	36	11
Scarlet fever	43	5
Cerebro-spinal meningitis	7	5
Measles	143	11
Diphtheria	83	24
Small-pox	0	0
Varicella	0	0
Pertussis	2	1

Hypnal is the name given to a crystalline compound formed by the mixture of strong solutions of chloral hydrate and antipyrine. Reuter has discovered that its chemical name is tri-chloral-dehyde-phenyl-dimethyl-pyrazol, but Bardet has mercifully called it hypnal. According to a note in the *British Medical Journal*, the latter has found that it is a very active body, which possesses at the same time the sedative and hypnotic properties of its constituents. It acts favorably in doses of one gramme only, and in twenty-two cases where it was administered sleep was obtained with facility. Hypnal is especially useful in insomnia, caused by pain and cough. It has neither the disagreeable taste of antipyrin, the causticity

of chloral hydrate, nor the irritating effects upon the stomach of its two constituents. It can be easily taken, especially by children; and it presents other advantages in consequence of the absence of taste. The process for making hypnal is very simple; it is only necessary to dissolve separately in the smallest possible quantity of water equal parts of chloral-hydrate and antipyrin, upon mixing the solutions a crystalline precipitate falls, which, after washing, can be immediately employed.

A Bad Place for Doctors.—A strange fatality, says the *Denver Republican*, seems to lurk about the office of the physician at the Devil's Lake Indian reservation, on the south side of the great lake. Within the past eighteen months the office has been filled by four different doctors, three of whom are dead and one totally incapacitated for practice.

A New Society, to be known as the Philadelphia Electro-Therapeutic Society, has been organized, with the following officers: President, Dr. G. Betton Massey; Vice-Presidents, Drs. J. Pearson Willits and Matthew J. Grier; Secretary, Dr. Wm. H. Wailing; Treasurer, Dr. J. J. Taylor. It starts with a membership of forty.

New Medical Colleges.—A new medical college will be started next October in Chattanooga, Tenn. It will be known as the Medical Department of the University of the South. It will require high preliminary knowledge and three full courses of lectures. Nebraska has a new medical school. It is located at Lincoln, Neb., and is known as the Medical Department of the Nebraska Christian University.

The Abuse of Hospital Relief.—It is not in London only that the misuse of hospitals is under anxious discussion. A Select Committee of the House of Lords is engaged at this moment in the endeavor to devise a remedy for a state of things which has been made glaringly evident by the testimony of many witnesses. In Melbourne the Medical Society of Victoria is engaged in a similar discussion. The Society has unanimously adopted the following resolutions:

"This Society is of opinion that (*a*) Great imposition on the part of well-to do people is practised at the public hospitals, which is contrary to the principle on which these institutions were founded, and on which they should be conducted. (*b*) All hospitals receiving Government aid annually should be devoted solely to the treatment of the destitute and poor. (*c*) Paying patients should not be admitted into hospitals receiving Government aid granted for the benefit of the destitute and poor. (*d*) A wage limit should be fixed for all hospital patients (*i.e.*, all those earning more than a certain amount should be excluded).

"That the circumstances of each applicant for admission should be investigated by an officer of the hospital appointed for the purpose, who should use wide discretionary power in special cases."

The United States might take a hint from their Australian cousins. As for New York, hints are hopeless persuaders.

The Cholera.—The attempts of the quarantine authorities at ports on the Black Sea and Caspian Sea to exclude cholera from Russia were successful last year when the disease prevailed throughout Mesopotamia and in other parts of Persia; but now, when very little is heard of cholera in the wide region then affected, the disease has gained a foothold at Baku, on the west coast of the Caspian Sea, where the great petroleum wells are situated. It may be difficult to confine it to that district. This epidemic and that which ravaged Mesopotamia last year were caused by the transmission of cholera germs from India by means of the pilgrimages from India to the so-called holy cities near the mouth of the Euphrates, or by the transportation of dead bodies from India to be buried near those cities. The disease might easily have been kept out of Mesopotamia and Europe by the enforcement of simple sanitary regulations at the head of the Persian Gulf.—*New York Times.*

The Microbe of Old Age.—This is the latest addition to the list of micro-organisms. The Italian physician who has just announced its discovery says that it may be transmitted by heredity. It is a dangerous microbe to handle, and young physicians are warned accordingly.

The British Medical Association is to open its meetings in Leeds on Wednesday, September 3d, when Sir F. Abel will deliver his address as President. Following precedent, the British Pharmaceutical Conference will open on Monday evening, September 1st.

A Students' Aid Organization at Paris.—M. Pasteur is the chairman of a committee, formed at the Sorbonne, for the purpose of encouraging foreign students to enter the University of Paris. It is proposed to assist strangers immediately upon their arrival in the city for the purposes of study, and to furnish gratuitously a kind of bureau of information and elementary advice.

The Deficient Water-supply of Paris.—It is a matter of surprise, says *The Lancet*, to all visitors of this gay city that the French, who assume to be in most things in the van of all other nations, should be so very backward in their water and sanitary arrangements in general. Each year as the summer returns a notice is published by the Municipal Council of Paris to the effect that owing to a scarcity of drinking-water this latter will have to be temporarily replaced by water from the Seine. Although only temporarily, the Municipal Council seem to forget that one single draught of this water may be sufficient to cause death, as it is now generally admitted that river water is the vehicle of the germs of typhoid fever, cholera, and of many other epidemic maladies. This arrangement does not extend to all Paris at the same time, but three or four arrondissements in succession are submitted to it for a term of twenty days. The excuse for this lamentable state of things is that the public coffers will not admit of the outlay necessitated by the arrangements for bringing spring water into this city, and yet millions are spent on less necessary purposes. It is all very well to open boulevards and squares, and to plant trees in all directions, but water is as indispensable as air. M. Ferdinand Duval, late Prefect of the Seine, in writing on the subject made the remark that water should not only be in sufficient quantity but in abundance, and a city in which the inhabitants have only a very limited supply of water at their disposal he compared to a ship in distress.

It appears that the senate has just voted the bill for supplying Paris with drinking-water from the Vigne Springs in the Avre Valley. It will be four years, however, before Paris feels the benefit of this decision, as the works cannot be completed before that period.

The Practice of Medicine in France.—According to a proposal recently made by the French Minister of Public Instruction, the lower grade of medical practitioners, *officiers de santé*, is to be abolished, and there is to be a single state examination, which will be the same throughout France. Foreigners will have to undergo all the examinations in order to obtain the licence to practise.

Medical Congress in Japan.—It was inevitable that the Japanese, who have shown so remarkable a power of assimilating the details of Western civilization, should before long hold a Medical Congress. Accordingly, the first gathering of the kind in Japan was held at Tokio, from April 1st to the 7th. In spite of the somewhat inauspicious day chosen for the opening, the meeting was a great success, though only two foreign doctors were present; as there are nearly forty non-Japanese practitioners at Tokio and Yokohama, some disappointment was felt that more of them did not grace the assembly with their presence. It is hinted, however, that the Invitation

Committee was chiefly responsible for the absence of the foreign element. The proceedings were of the usual kind: addresses on various more or less interesting subjects being delivered, cases and inventions, new and old, exhibited, etc. Complaint is made in some quarters that the scientific communications were not sufficiently inspired by the *genius loci*, little or nothing of special interest to the Japanese people being contained in them. As compared with other congresses, festivities seem to have been few and far between, though we are told that on the last day there was a "general social gathering in Shiba Park, at which there was an ample provision for refreshment."—*The British Medical Journal.*

The Study of Medicine in Portugal.—The medical students of the University of Coimbra have addressed a petition to the King of Portugal, praying for the abolition of the examination in Greek, which, by a refinement of cruelty only known to the pedagogic heart, is reserved for the final year of the curriculum. The petitioners, who argue their case with much force, point out that the time allotted to medical study is all too short to enable them to meet the ever-growing requirements of their examiners, and that it is unfair to hamper them with a subject altogether outside their ordinary work just when they should be putting the final touches to their professional training. It appears from this document that the whole period of study which must be gone through by aspirants to a medical degree at Coimbra is fourteen years, of which six are devoted to "secondary" or ordinary school education, three to a preliminary scientific course, and five to purely medical study.

Successful Exsection of a Neoplasm of the Liver.—The surgery of the liver is progressing rapidly, and in Vienna they quite often remove the gall-bladder for cholelithiasis. In a case at Albert's clinic, Hochenegg removed a gall-bladder containing fifty-two gall-stones, and as the walls were carcinomatous he examined the liver carefully for metastasis. He found but one metastatic deposit near the anterior border, removed it with the knife, sewed the peritoneum all around the wound, and finally sewed up the abdomen in such a manner that the wounded liver could be seen from without. The extirpated portion was one by one and one-half inch in size. It is now over nine months since the operation, and there seems to be no recurrence. The case is interesting because it is believed to be the first where a neoplasm was removed from the liver with good result.—Vienna Correspondence, *Medical News*, July 26, 1890.

Medical Inspection of Immigrants by Consular Physicians.—It is stated that the United States Marine Hospital service has decided to establish physicians at every port in Europe from which immigrants embark to this country. These physicians will work under the supervision of the United States Consul at the port where they are stationed. It will be their duty to examine immigrants intending to sail for this port, and to prevent the embarkation of the great army of the lame, the halt, and the blind, who for years have been pouring into this country, only to fill up the county and State pauper institutions. Particular attention will be given to rejecting people suffering from contagious diseases and all affections of a scrofulous nature. The plan proposed has been successfully carried out in connection with the Marine Hospital Service in West Indian and South American ports, and the effect of this protection to the United States in the exclusion of contagious diseases is considered inestimable by the members of the service. Thus, while yellow fever is raging at Santos and Rio Janeiro, Brazil, there is very little danger of its getting into New York, even in the summer season. In connection with this work, the European consuls are expected to also make examination, particularly with regard to criminal cases and those who claim to be citizens of this country. If the candidate proves to be actually a citizen, the consul will issue to him a certificate. It is understood that women about to become mothers will also be included in the class to be kept from embarking.

Eighty Physicians are Members of the French Parliament.—Forty-eight of this number are deputies and thirty-two are senators. How many medical congressmen or senators do the people send to Washington?

The Lunier Prize.—The French Temperance Society against the use of alcoholic beverages have received from Mrs. Lunier one thousand francs, to be called the Lunier prize, to be given to the author of the best essay on the following questions: What are the consequences of hereditary alcoholism, and what are the best means of prevention, or means to limit or lessen its effects? Authors are expected to follow out the lines of inquiry suggested in Lunier's work "On Alcoholisms." The society does not limit this study and research, but wishes it to embrace all the questions of moral, social, and therapeutic means, for prevention and restoration of inebriety. The society will accept parts of printed works, as pamphlets, on this topic that have appeared before January 1, 1890, associated with what has been written since this date, to compete for the prize. All manuscripts should be received before December 31, 1890, and should be addressed, Dr. Motet, secretary-general of the French Temperance Society, 161 rue de Charonne, Paris, France.

Observations on Somnal.—Somnal is a compound or mixture of chloral, urethan, and alcoholic ethyl. It appears as a colorless fluid which, on cooling, takes the form of needle-shaped crystals. It has a bitter taste. It has been tried with good results by Dr. Constantin Paul in articular rheumatism, and also by Dr. Guttmann, who found that it produced a pleasant sleep lasting from six to eight hours, without any bad effects. (*The London Medical Recorder.*) In some cases, however, it fails in its action. Dr. Zagorski, of Warsaw, prefers it to all other hypnotics for the rapidity of its action, the duration and intensity of the sleep, and for the absence of any effects upon the bowels, the heart, the lungs, and the general temperature. The dose recommended is about thirty grains in a little distilled water and syrup of orange. It is deliquescent and soluble in water, and in one-third of its weight in alcohol. Others have treated it as a mixture of uncertain composition, of a bad, bitter taste, and less powerful than chloral. Lutze found it only efficacious in thirty per cent. of his cases, and only useful in fifteen per cent.; and in eight cases of great excitement it was found to act more quickly than in chloral. Drs. Venanzio and Sighicelli, of Milan, have tried somnal in eighty patients in doses of from two to four grammes. In some few cases they went as high as six grammes. The general results observed by these physicians were as follows: Somnal produces no gastric disturbance and neither affects the appetite nor the digestion. Sometimes the pulse becomes more frequent and weaker a little while after taking the drug, but this effect soon passes away. Somnal has no action on the respiration, but sometimes produces a redness of the face dependent upon paralysis of the vessels, which is easily increased by the addition of a small quantity of alcohol. In doses of thirty grains somnal may be used for slight restlessness, but in cases of deep insomnia, dependent on cerebral excitement, it is necessary to give as much as sixty grains, which generally produces a sleep of from five to six hours. It rarely happens that sleep comes on in half an hour; in general it takes about three hours, sometimes even as much as four or five, till the desired effect is obtained. In cases accompanied with mental depression, somnal acts better than where there is much excitement. On the whole, they consider that somnal is a useful hypnotic, from the duration and quality of the sleep which it induces, from its having no bad effects, and also from its small cost. In its therapeutic effects it has a resemblance to its two principal components, chloral and ether.

APPENDICITIS.[1]

BY FRANK HARTLEY, M.D.,

NEW YORK.

THE importance of a proper appreciation of the condition known as appendicitis can scarcely be overestimated when we consider the varied opinions expressed by surgeons of the proper course to pursue in its treatment. One operator will justify the use of the needle, another will consider this procedure dangerous. Others prefer a conservative treatment until an abscess is formed. Others wish to operate immediately before the disease has any of its complications. Some, again, tell us that we are to make a differential diagnosis between a spreading and a circumscribed peritonitis, and if spreading to perform laparotomy; if circumscribed, to wait and open the abscess, if such is present, at any time after a week. They tell us, moreover, that we are to make a differential diagnosis in the first twenty-four, forty-eight, or seventy-two hours of the attack, and in cases of doubt the exploration is less dangerous than delay. On the other hand, physicians who certainly see many of these cases early in course, recount many cases of resolution of the disease in which the local and constitutional symptoms were severe, and in which no recurrences followed. From this medley of opinion we must draw our conclusions in accordance with what we have learned from the histories, imperfectly recorded, and autopsies, indefinitely stated, or made at a time when the disease has already run its course. What we require at the present time is a collection of cases operated upon for this disease, as well as of those cases treated expectantly. From such a comparison we may be able to arrive at a just conclusion in the matter as to what varieties are to be treated in the one or other manner. No method of study, it appears to me, can be considered complete without the records of cases operated upon by abdominal incision, in which are given, as seen at the operation, the exact location and extent of the disease, the variety of the appendicitis, as well as the variety and extent of the complicating peritonitis.

In the Roosevelt Hospital during the last two years fifteen cases have been operated upon in this manner, and carefully recorded histories have been kept. Other cases have been operated upon, but they could not be used, either from the want of accurate histories or from the method of operation.

Of these cases 12 were males and 3 were females. The youngest patient was ten years of age; the oldest was thirty years of age. The average age was seventeen years four months. The duration of the disease from the first attack was, in 1 case, 2 days; in 2 cases, 9 days; in 1 case, 3 days; in 1 case, 12 days; in 2 cases, 4 days; in 1 case, 14 days; in 2 cases, 6 days; in 1 case, 17 days; in 1 case, 8 days; in 2 cases, 5 months; in 1 case 6 years. Twelve of these cases were operated upon in their first attack at periods as follows: second, third, fourth, fourth, sixth, sixth, eighth, ninth, ninth, twelfth, fourteenth, and seventeenth day of the disease. One case was operated upon on the third day of the second attack. The first attack antedated this six years. One case was operated upon on the second day of the third attack. The first attack antedated this five months. One case was operated upon on the nineteenth day of the third attack. The first attack in this case antedated this operation five months.

The location of the appendix in reference to the cæcum was as follows: Below and partly behind the caput coli, 1; behind the caput coli, 8; below the caput coli, touching the anterior abdominal wall, 1; below and partly in front of the caput coli, 1; over the brim of the pelvis internal to the caput coli, 1; inner side of the caput coli, 1; on the anterior surface of the caput coli, 1; behind and to the inner side of the caput coli, 1.

This relation of the appendix to the caput coli is given because of its importance to the surgeon both in the diagnosis of the disease and in the method of operation. The point representing the junction of the cæcum and the vermiform appendix lies opposite a point marked by the middle and lower thirds of a line passing from the umbilicus to the middle of Poupart's ligament. These two facts—the relation of the appendix to the cæcum and point of union of the caput coli and appendix—give the best explanation in many cases for the seat of most intense pain on pressure, as well as in many cases the presence or absence of a distinct tumor in the iliac fossa.

As to the varieties of appendicitis we find four cases of catarrhal appendicitis.

1. A simple catarrhal inflammation with no adhesions except to the caput coli near its base. These adhesions were very slight, and occupied a space easily covered by the end of an ordinary lead-pencil. The operation took place on the fourth day of the first attack. It presented a distinct constriction just below its cæcal extremity.

2. A catarrhal inflammation with minute and isolated purulent foci throughout the walls of the appendix, but with no adhesions between it and the neighboring intestines. It presented a slight constriction near the cæcal end. The operation took place on the fourth day of the first attack. This case appears to represent the step between a well-marked catarrhal and a purulent inflammation of the appendix. This case has been placed in this division simply because its catarrhal character was well marked, and the purulent very slightly so.

3. A simple catarrhal inflammation of the appendix without adhesions The disease existed only at the very end of the appendix. No constriction was found in the appendix. The operation took place on the third day of the first attack.

4. A chronic catarrhal appendicitis with greatly hypertrophied walls. In this case many strong adhesions bound the appendix to the small intestine and caput coli. It presented a slight constriction near the cæcal end. The operation took place on the second day of the third attack.

There are four cases of suppurative appendicitis.

1. A suppurative appendicitis in which a well-marked constriction existed near the cæcal end, with a perforation just below the constriction. Operation took place on the third day of the second attack. The first attack antedated the present one six years.

2. A suppurative appendicitis in which no perforation nor constriction could be found. The operation took place on the eighth day of the first attack.

3. A suppurative appendicitis showing no constriction nor perforation. The operation took place on the sixth day of the first attack.

4. A suppurative appendicitis in which the appendix

[1] Read before the Fortnightly Medical Society, New York.

was so much damaged that it was impossible to tell accurately about the presence of a constriction. The operation took place on the ninth day of the first attack.

There are five cases of gangrenous appendicitis.

1. A gangrenous appendicitis in which a well-marked constriction was noticed near the cæcal end. The operation took place on the second day of the first attack.

2. A gangrenous appendicitis in which a well-marked constriction existed near the cæcal end. There was a point of perforation just below the constriction. The operation took place on the fourteenth day of the first attack.

3. A gangrenous appendicitis in which was found a large concretion, and in which there was a point of perforation just below the constriction and above the position of the calculus. The operation took place on the sixth day of the first attack.

4. A gangrenous appendicitis in which no constriction could be found. The operation took place on the ninth day of the first attack.

5. A gangrenous appendicitis in which no stenosis was observed. The operation took place on the seventeenth day of the first attack.

Two cases were operated upon on the twelfth and nineteenth days of the first and third attack, respectively, in which no distinct appendix could be recognized. When we examine these cases we find that the five gangrenous appendicites showed a distinct point of perforation in 2 cases; the four suppurative appendicites in 1 case. In 15 cases only 1 case showed a concretion; 7 cases in 15 cases showed a distinct point of constriction nearer the cæcal than the distal end. This fact was impossible to determine in some cases accurately, especially if the constriction occurred near the point of ligature, or where the appendix was already separated from the cæcum, or where the appendix was, more or less, completely destroyed.

The varieties of peritonitis occurring in the course of these cases was as follows: The catarrhal appendicitis (acute) (3) were either not complicated at all by peritonitis (2), or where this existed was limited to a few adhesions here and there between the appendix and the neighboring intestines (1). The exudate consisted of fibrine alone. The single case of chronic catarrhal appendicitis presented well-marked and very dense adhesions to the intestines, cæcum, and iliac fossa. The purulent appendicitis (4) presented in all cases a peritonitis fibrino purulent and purulent. The gangrenous appendicitis presented either a fibrino-purulent and purulent peritonitis or one attended with a foul-smelling sero-fibrinous exudate. In ten cases this peritonitis was circumscribed. In three cases it was circumscribed and diffuse, *i.e.*, progressive. The circumscribed peritonitis was present—

1. In a case of acute catarrhal appendicitis. The peritonitis was fibrinous.

2. In a chronic catarrhal appendicitis operated upon on the third attack. The peritonitis was one in which dense and strong connective tissue bound together the appendix, cæcum, intestines, and peritoneum covering the iliac fossa.

3. In four cases of purulent appendicitis where the operation occurred upon the third day of the second attack, and upon sixth, eighth, and ninth days of the first attack. In these the peritonitis was fibrino-purulent and purulent.

4. In two cases of gangrenous appendicitis operated upon on ninth and seventeenth days of the first attack. The peritonitis was fibrino-purulent or purulent. If we include in these cases the two cases in which no distinct appendix could be demonstrated, we will have four cases of gangrenous appendicitis followed by a circumscribed fibrino purulent and purulent peritonitis, and operated upon the ninth, twelfth, seventeenth, and nineteenth days of the first attack.

The circumscribed and diffuse peritonitis combined (*i.e.*, the progressive) was present in three cases of gangrenous appendicitis.

1. The operation took place upon the fourteenth day of the first attack. The peritoneum in the immediate neighborhood of the appendix was covered with a serofibrinous exudate. In the rest of the peritoneal cavity, except in the neighborhood of the diaphragm, the exudate was either fibrinous, fibrino-purulent, or purulent. This variety of exudate was about equally present in every region examined. The fluid within the cavity was serofibrinous, bad-smelling, and in places somewhat greenish in hue, and attended with the formation of gas. The presence of gas was evident in the immediate neighborhood of the appendix, but throughout the rest of the abdominal cavity it was wanting.

2. The operation took place on the sixth day of the first attack. In the immediate neighborhood of the appendix the exudate was distinctly purulent. Beyond the appendix, between the coils of intestines, the exudate was sero-fibrinous and bad-smelling.

3. The operation took place upon the second day of the first attack. The exudate both in the neighborhood of the appendix and beyond it was distinctly fibrino-purulent and purulent.

The height of the temperature seems to be of very little value in telling one the conditions within the abdomen, either in reference to the condition of the appendix or the complicating peritonitis.

Two cases of simple catarrhal appendicitis with no adhesions had no rise of temperature. One case of simple catarrhal appendicitis with small purulent foci (a beginning purulent appendicitis) had a temperature of 102° F. One case of chronic catarrhal appendicitis during such a circumscribed fibrinous peritonitis, the third attack, had a temperature of 102° F. In four cases of purulent appendicitis with circumscribed fibrino purulent and purulent peritonitis the temperature was 100.4°, 103.4°, 100°, 100° F. In four cases of gangrenous appendicitis with circumscribed fibrino-purulent peritonitis the temperature was 101⅘, 100°, 101°, 99° F. In three cases of gangrenous appendicitis with a circumscribed and diffuse peritonitis (*i.e.*, progressive) the temperature was 101° F.; one not known, 103° F.

These were the temperatures taken upon admission and do not represent the elevation of temperature at the commencement of the attack. The height of the temperature has no value, but a remittent or intermittent one is of great value when considered with other important symptoms.

The temperatures following the operation were practically normal, except in two cases of gangrenous appendicitis with diffuse progressive peritonitis which died.

The average time required in the treatment of these cases was forty days. The number of deaths occurring in these cases was three.

1. On the second day after the operation.
2. At the end of the third week.
3. Fourteen hours after operation.

The causes of death were:

1. Diffuse septic peritonitis—septicæmia.
2. Diffuse septic peritonitis—septic pneumonia-pymiaæ.
3. Circumscribed peritonitis—septicæmia.

If we divide our cases into the four varieties included in this list we can give three cases of catarrhal appendicitis with no adhesions present, in one of which the appendix showed purulent foci not yet involving, however, the peritoneal coat. They were, practically, cases of catarrhal appendicitis and were operated upon the third and fourth days of their first attack. In none were adhesions present. In two, stenosis more or less marked existed at the cæcal end. In two cases the temperature was normal at the time of operation. In one case with purulent foci the temperature was 102° F. In two of these cases the pain, which was at first general, was localized on the second day to the right iliac fossa.

We have one case of chronic catarrhal appendicitis

which was operated upon the second day of the third attack. It showed a chronic catarrhal inflammation with greatly hypertrophied walls. Stenosis was present near the cæcal end, and chronic plastic peritonitis was present. The temperature during this attack was 102° F. The pain was at first general, and was localized in the right iliac fossa on the second day.

We have also four cases of suppurative appendicitis. These cases were operated upon the third day of the second attack (the first attack was six years before), and upon the sixth, eighth, and ninth days of the first attack. Stenosis was marked in one case in which there existed a perforation. In the other three cases such was not noticed. No calculus was present in any of these cases. The peritonitis in all was fibrino-purulent, or purulent and circumscribed. The temperature was 100.4°, 103.4°, 102°, 100° F. They were all characterized by general abdominal pain, which was localized in the right iliac fossa on the first, second, and fourth days. In none of these cases was tympanites marked, and in none was prostration to any extent evident.

Of the gangrenous appendicitis we have five cases. They were operated upon the second, sixth, ninth, fourteenth, and seventeenth days of the first attack, and if we include in this variety those cases in which no distinct appendix could be found we have 2 cases operated upon the twelfth and nineteenth days of the first attack. In two cases stenosis was present, and in one a calculus was found. In 2 cases a perforation existed. In all cases the variety of peritonitis, fibrino-purulent and purulent, or a foul-smelling fibrinous exudation, was present upon the intestines. In 4 of the cases the peritonitis was circumscribed and fibrino-purulent and purulent, and in 3 cases there was circumscribed and diffuse peritonitis (*i.e.*, progressive), and the exudation was fibrino-purulent or fibrino-serous, with gas formation. The temperature in those with circumscribed peritonitis was 101⅘°, 100.4°, 103° F. In those cases with a progressive peritonitis it was 101°, 103° F. not known.

The pain in three cases was at first general, and was localized in the iliac fossa, in 1 case upon the third day, in 1 upon the fourth day, and in 1 the exact day could not be determined. In 2 cases the pain was in the right iliac fossa from the commencement of the attack. In the other cases the statements of the patients could not be relied upon. Tympanites was present in 3 cases, and wanting, or at least slightly marked, in 2 cases. Prostration was noticed in 4 cases, and of these 3 died.

I wish here to state that all cases of chronic catarrhal appendicites do not by any means show the conditions existing in the above case. I have seen 3 such cases which were operated upon in their third, fourth, and fifth attacks, in which no adhesions existed between the appendix and the surrounding intestines. Their walls were greatly hypertrophied, and presented, near their cæcal ends, constrictions, but the peritoneal coat was in all cases absolutely uninvolved. (Though these cases were operated upon by abdominal incision they could not be used for want of accurate histories.)

These fifteen cases appear to me simply as degrees of infection in an appendix already the seat of a catarrhal inflammation with a stenosis at the cæcal end, the result of the inflammatory swelling alone, or of a previous inflammation, with new connective-tissue formation. There appear to be no accurate symptoms which will allow one to state definitely either the condition of the appendix or the probable course of the disease, except the presence or absence of its complicating peritonitis. Nor does the severity or mildness of the initial symptoms seem to give us anything valuable either in a diagnostic or prognostic sense. We cannot regulate the condition within the appendix by time alone, as many, I think, suppose. We have seen in these cases alone catarrhal appendicitis on the third and fourth days, a catarrhal appendicitis with purulent foci within the walls of the appendix and with an intact peritoneal investment on the fourth day.

On the third day of the second attack a purulent appendicitis with a circumscribed fibrino-purulent peritonitis was present, and upon the sixth and eighth days of the first attack the same condition has existed with the same intensity in symptoms.

Moreover, upon the sixth, ninth, and seventeenth days of the first attack we have found the appendix gangrenous, with a circumscribed peritonitis; and upon the second, twelfth, and fourteenth days of the first attack the appendix was found gangrenous, with a circumscribed and diffuse peritonitis. The temperature elevation has been of no value in these cases in a diagnostic sense. The severer cases often run their course with very little elevation of temperature. What is of more value is the remittent or intermittent character of the temperature.

Yet there are symptoms which seem to be diagnostic of appendicitis in some of its phases. In that variety where the perforation is sudden, no matter whether it be from an appendix free from adhesions or from the small abscess cavity in which the appendix lies, and the whole peritoneal cavity is at once invaded, the thready and rapid pulse, the cold perspiration, the cool extremities, and the moderate cyanosis, with or without a tensely contracted abdomen and distention of the abdominal cavity, are symptoms of value, especially when combined with a severe circumscribed or diffuse pain starting from the right iliac fossa. Though the vermiform process may be found in all portions of the abdomen except in the left hypochondriac and lumbar regions, the pain, when localized in the right iliac fossa, is important and is reliable in diagnosis. Moreover, in just this variety the history is of extreme importance, for we find it occurring either during the course of a well-marked appendicitis from rupture of the abscess (the cavity in which the appendix lies), or we find that preceding the present severe symptoms there is a history of previous attacks of appendicitis occurring with some regularity. Should the latter not be the case, the history is often one of severe intestinal colic treated from time to time. In the diagnosis of any case of appendicitis we are to always consider the great variety of conditions which may simulate it. In the acute cases the peritonitis is sometimes the first symptom, and if no trauma existed it is no easy matter to decide upon the focus. Many other processes may lead to a peritonitis under similar circumstances. Every abdominal organ when diseased—echinococcus cysts, incarcerated volvulus, ileus, and typhoid fever may simulate perfectly cases of appendicitis attended with a perforative (*i.e.*, septic or progressive) peritonitis. Twelve cases of appendicitis which ran their course without other symptoms than those of an internal strangulation of the intestines have been reported by Ransohoff. I have myself seen two such cases in which an operation was performed for an internal strangulation, and which proved to be intestinal obstruction from adhesion to the wall of the abscess formed by a gangrenous appendix. I know of two cases of multiple abscess on the liver due to an appendicitis, with phlebitis in the ileo-cæcal vein, in which the diagnosis was impossible either from the history or the symptoms at the time of operation. I firmly believe that many cases are due to an extension of inflammation from the cæcum, and should this remain catarrhal may resolve in ten days to two weeks.

That such cases do occur there can scarcely be a doubt. Certainly many have had the symptoms belonging to an inflammation in this organ and have never had a second attack, and that period of immunity has lasted six, eight, to ten years. Such results, so far as I can ascertain from comparison with the early cases removed, depend entirely upon the grade of the appendicitis and the obstruction to the escape of the contents into the cæcum from the swelling of the mucous membrane at the cæcal end, or possibly to inspissated fecal masses in the cæcum. Such cases cannot be diagnosticated, however, from those in which stenosis exists and persists at the cæcal end, and which run their course as an intestinal catarrh, with colic, slight fever,

no tumor and no dulness, since the appendix is behind the cæcum, but which eventually give rise to circumscribed or progressive peritonitis from perforation or gradual extension of the inflammatory process. The slower such a process advances the easier the diagnosis. Our duty is to recognize as early as possible the position of the focus, the extent of the peritonitis, and the position of the puriform collection. An examination every few hours for the percussion note, the pain, and the resistance over the appendix will allow one to decide upon the circumscribed or diffuse character of the peritonitis. The increase and extension of the area in which the symptoms are found, together with a continuous high temperatue or a tempera ture with a repeated rise and short remission, lead us to think of a progressive, and possibly a diffuse, peritonitis, with the formation of new foci within the peritoneal cavity. A matter never to be omitted in the diagnosis of these cases is the rectal and vaginal examinations, as well as the presence of the Howship-Romberg symptoms. These are of extreme importance in locating the position of the focus, as well as in selecting the proper place for incision.

Our methods of treatment in the complications following appendicitis have not yet arrived at that point of perfection where we can feel certain, or even moderately so, of overcoming the disease when it has already advanced in its course. Although from the class of cases seen by the surgeon in the majority of cases early interference alone seems the proper course, still, the fact that we are opening up a field for infection, the extent of which is nearly equal to the entire cutaneous surface, and the rapidity of absorption is equal to three to eight per cent. of one's weight of fluid in an hour, is not to be viewed without concern. Nor can the danger of a peritonitis originating from the intestinal canal, of a perityphlitic abscess, of a fibrinous or fibrino-purulent peritonitis if no abscess exist, or of a gangrenous appendix, be entirely overlooked. Such infective foci are best treated when removed completely. When the disturbance in the absorptive and transudative processes in the peritoneum is negatived the decomposition of exudate within this dead space is stopped, and the amount of poison produced is reduced to that which can be absorbed and eliminated by the excretory organs. On the other hand, the peritoneum is a very tolerant surface to infection under conditions where aid is given to encapsulate that poison by the removal of the focus of infection and the relief of the passive hyperæmia in the neighboring peritoneal coat, so necessary for the growth and extension of the infection. Such aid is best secured by the limitation of the infection to an area over which we have complete control by antiseptic measures and drainage. We cannot compare in virulence, as many wish to, the perforative peritonitis from the vermiform appendix with those from the stomach or upper portion of the intestinal tract. The conditions for advance of the perforation are entirely different. The infectious peritonitis following perforation of the stomach or of the upper intestinal tract, even if encapsulated in the supraomental space, is more frequently followed by septic or progressive and diffuse peritonitis from the peristaltic action of the intestines than is the case with the vermiform process, or occurs in puerperal peritonitis, where adhesions inclose the infecting focus and retard its advance. Nor do I believe that much reliance can be based upon the fact that the slow ulceration which generally follows in the vermiform process, and the small amount and hardness of its contents render it less dangerous, as many suppose. If the focus remain, though encapsulated, it is subject to injury from slight errors in diet, vomiting, purging, etc., and at any time we may have here, as in every true phlegmon within the peritoneal cavity, the danger of the extension of the inflammatory process. In the treatment of this disease we should decide upon one or another method, depending upon what the pathological condition is. The indiscriminate use of any one method for all cases, though it may relieve many, is certainly not very surgical when we compare the dangers of the various methods with the dangers of the variety of disease.

We will divide these cases into—1, those in which in the first attack a complicating peritonitis already exists at the time we see it, either a septic, progressive, or circumscribed; 2. into those in which the disease, as yet, is confined entirely to the vermiform process—catarrhal appendicitis; 3, into those in which recurrent attacks of catarrhal appendicitis have occurred, and in which adhesions have bound the appendix to the cæcum, intestines, or peritoneum, over the iliac fossa or not.

In the acute and peracute infectious peritonitis, depending either upon rupture of the vermiform process or of the abscess cavity about it, and in which we find the symptoms of a marked intoxication, whatever is to be done must be accomplished at once.

In the peritoneal cavity we find either the peritoneum slightly infected and covered with a vail of thin fibrinous exudate, or, more rarely, this exudate is thick. The fluid exudate varies in amount and kind. It is either bloody, serous, comparatively odorless, and small in amount, or bad-smelling and stinking, and in large amount, and generally found most abundantly in the region of the kidneys and in the smaller pelvis. The whole peritoneum seems infected, except possibly in the region of the diaphragm. The most striking characteristic of this form is the absence of adhesions and the localization of the infecting focus.

In this class we all admit that the only chance lies in operative interference. We must also admit that, so far, the attempts have been almost absolutely unsuccessful. Only in the very early operation, and in a patient in relatively good condition, can we hope, with our present means, to save a case. Our bad results to-day seem to be due to our inability to thoroughly disinfect the peritoneum and to limit the amount of infection, either by liberation of the exudate, washing, sponging, or drainage. The intensity of the infection, the sudden onset, the want of encapsulation, and the great absorptive power of the peritoneum are more than equalled by our ability to disinfect thoroughly, to drain properly, and to act at a time when the infection has not already overwhelmed the patient.

In the second form of peritonitis the whole peritoneum is not attacked at once. The course of the disease is not so rapid. It is subacute, or at most acute. It advances gradually from the focus of infection, either by small perforations which are quickly encapsulated, or by a gradual extension of the process *per contiguitatum*. The characteristic of this form is the encapsulation of the advancing area by peritoneal adhesions or by fibrino-purulent exudates upon the peritoneum covering the intestines; within the spaces left by these adhesions a fluid, purulent exudate is formed. These centres are separated from one another by coils of intestines, and constitute *en essence* separate and distinct abscess cavities between the intestines. This process advances until the whole peritoneal cavity is involved. The involvement of the whole peritoneal cavity rarely occurs in this form, however, as death occurs before it has advanced to this extent. Of course, the slower such a process advances the more marked are the adhesions and the encapsulation of the primary exudate and the more the exudate resembles a true pus. In very slow cases the purulent foci may empty externally or into an internal organ and a natural cure result. More frequently, however, the patient succumbs before this stage is present, or dies of pyæmia. Between this variety and the former—septic peritonitis—there are many variations in degree, so that it is often very difficult to decide to which of the classes any particular case belongs. The more and more any variety approaches the progressive peritonitis the better will be the prognosis, for these adhesions enclosing the separate foci offer a protection more or less complete against the further involvement of the intact peritoneum. These adhesions must in every operative procedure be left untouched, should it be possible to do it, and at the same time liber-

ate completely the exudation. I am fully convinced that some cases of progressive peritonitis are followed by death, shortly after operation, from a too extensive breaking up of these adhesions and the induction of a diffuse and septic peritonitis, *i.e.*, peritoneal sepsis.

Our duty in this class of cases is to see clearly and to thoroughly remove the primary foci (or at least to render it innocuous), and with the utmost care to open separately the isolated foci, without endangering the intact peritoneum, if possible. So far as the circumscribed peritonitis complicating appendicitis is concerned, we should treat it according to the recognized rules of surgery. It cannot be doubted that to wait for the absorption of such a focus is attended with too much danger of its extension to the peritoneum, of its rupture into the bladder or rectum, or of pylephlebitis or pyæmia. Nor do I think it justifiable, in order to determine whether more or less purulent fluid is present, to make use of the needle. I cannot believe that the puncture of the intestines can be done without danger. In so doing we expose our patient to the very danger we are expected to avoid. In many of the cases I have seen, the position of the abscess was such that, had the needle been used, in fully one-third the intestines would have been punctured. Nor do I see any advantage in waiting until the tumor is larger and certainly contains pus, in order to operate extraperitoneally. The want of a complete resolution and the presence of a circumscribed peritonitis are sufficient grounds for an exploratory incision, performed either in the outer border of the rectus, if Dr. Sands's operation is to be performed, or if not, a median exploratory laparotomy, and an extraperitoneal operation for drainage alone.

In the chronic catarrhal appendicitis which I have seen, the condition has always been one in which the walls of the vermiform process were hypertrophied, and in which a well-marked stenosis existed near the cæcal end. The cavity below the constriction contained very little or no appreciable amount of fluid (not true pus).

Of the cases which I have seen, three were operated upon in their third, fourth, and fifth attacks, and had no adhesions to the intestines about them. One, stated in this paper, had marked adhesions, and was operated upon on the second day of the third attack. These cases are what we call recurrent appendicitis, which we imagine undergo a complete resolution after each attack, or what is called recurrent appendicitis without a complicating peritonitis. I think from the number of attacks, from the condition found within the appendix, and from the relief from subsequent attacks and the uninterrupted course of recovery from the operation, we are justified in operative procedure in all such cases as being the only means of absolute relief. These cases all run their course as simple catarrhal appendicitis, with or without involvement of the peritoneum, *i.e.*, plastic peritonitis; but we must remember that this is not always the outcome of our recurrent cases. Both suppurative and gangrenous appendicitis occur sufficiently often (6–21 Roux) in recurrent appendicitis to render our prognosis very uncertain as to the outcome of any given case. Such varieties occur not only in the earlier recurrences, but even at periods varying from five to seven years. An example of such a case is to be seen in two of the suppurative peritonitis here recorded.

The circumscribed suppurative peritonitis was present at the time of the operation, *i.e.*, third day of the second attack, whereas the first attack was six years before.

Many other examples may be found in the recent articles upon appendicitis, especially Hemans, Worcester, and Roux. I remember only too well two cases occurring, of physicians in this city, of diffuse septic peritonitis as the result of a recurrent appendicitis. In my own opinion, the recurrence of the appendicitis means a condition of the vermiform appendix requiring its removal to do away with the danger of subsequent attacks. In the acute catarrhal appendicitis seen in their first attack we are unable to tell from any of the prominent symptoms what will be the outcome; and yet we are all aware that by far the greater number recover from their first attack with at least an apparent resolution, and that about twenty-two per cent. (Kraft), eleven per cent. (Fitz), of these cases have recurrences sooner or later, which may take any course ending in peritonitis—septic, progressive, and circumscribed—in phlebitis, perforations into other organs, or in pyæmia. I do not believe that every acute case means operation, although I must admit that the majority of cases I have seen operated upon were complicated with either peritonitis in one of the above forms, or failed to undergo a complete resolution. The best course to pursue in these acute cases is the expectant one, unless a complicating peritonitis is present or resolution does not occur early, when an immediate operation is the only proper course. The future method of study should be directed to this end, viz., to know how many cases have recurrences, the character of the recurrences, the characteristics of the cases which recover and in which no recurrences take place, as well as the relative number of cases having complications during their first attacks. Until the disease is studied in this particular, the opinions of the surgeons and physicians will be at variance. Certainly from the stand-point from which the surgeon views this disease, seeing it before and during the operation, seeing constantly his inability to diagnosticate the conditions exactly, the belief in the operative treatment is not to be wondered at. The condition of the appendix cannot be determined accurately, so far as symptoms are concerned, and must, I think, after all, be made out entirely from an acquaintance with the disease as seen by those who make use of the abdominal incision, and who see clearly each time they operate the exact condition about and within the appendix.

As to the method of treatment to be carried out in these cases I certainly favor that one inaugurated by the late Dr. H. B. Sands, the object of which is to obtain a clear and complete view of the appendix; to remove the appendix, or at least render it innocuous; to render all dead spaces aseptic, and to maintain them so by drainage.

The incision to the outer border of the rectus muscle has the advantage of approaching the appendix at its point of union with the cæcum. The general rule, however, is to make the incision over the point of the tumefaction, so as to expose clearly and distinctly the focus. In suitable cases, either from the location of the abscess or in progressive peritonitis with puriform collections between the intestines, this lateral may be combined with a median laparotomy.

The danger of infecting the intact peritoneum is not great, if care is taken by the assistant, even when a large quantity of pus is present. Only those adhesions which bind the intestines over the focus should be separated. All other adhesions should be left undisturbed, unless one suspects behind them collections of purulent fluid. In this manner the smallest possible danger is offered for the infection of the intact peritoneum, as the assistant has only a small area of intact peritoneum to protect.

The treatment of the cavity left after removal of the fluid and the appendix is, I think, often overdone. The rubbing of iodoform powder over this surface with the finger, or the gentle sponging with 1 to 500 or 1 to 1,000 $HgCl_2$ is sufficient.

Irrigation of these cavities, under high pressure by means of tubes in the depth of the wound, which cannot be seen and controlled, is dangerous from rupturing of adhesions and infection of the general cavity. Irrigation under low pressure, with tubes which can be controlled, has no great advantage over the sponge or iodoform powder.

These exudates upon the intestines, forming the walls of the cavity, although they contain masses of bacteria, are to be looked upon as nearly harmless in the place where the exudate exists, for absorption here is greatly diminished. They are able, by remaining, to give rise to abscess of greater or less extent; yet it is more dangerous to remove

or injure them to any extent and to open up ways of infection. One can rely upon the gentlest sponging of these cavities with 1 to 500 or 1 to 1,000, or iodoform powder, if he will add to this some method of complete drainage.

In reference to the drainage of these cavities I have made use of a posterior drainage in several cases, in addition to the drainage through the anterior wound. The anterior tube and gauze, where the posterior is used in addition, can generally be withdrawn early. Indeed in most cases which I have seen the anterior drainage is of little value after a day or two, if the posterior tube fits well, is large, and is placed at the bottom of the cavity. Another advantage offered by the posterior tube is the possibility of bringing together the wound in the abdominal parietes much sooner and avoiding the tendency to a subsequent hernia.

This is a point to be considered in this operation. I have seen, myself, five cases of hernia following this operation, and I have heard of others. In one of the cases I saw the hernia was a strangulated one which was reduced by taxis.

This posterior drainage also has an advantage in those cases of circumscribed peritonitis with appendicitis where the abscess is situated in the iliac fossa behind the cæcum, or close to it, and where the tissues are sloughy and where the appendix as such cannot be recognized. These are the cases often followed by herniæ or fistulæ, and in just these cases, if the posterior drainage is complete, these dangers are reduced to a minimum. In inserting the tube I have protected the cæcum and small intestines forming the wall of the cavity with my right hand spread out in the shape of a cup; then, with the left hand, cut from without inward, as near as the outer border of the quadratus lumborum as possible, and thus entered the bottom of the abscess cavity. Where these cavities exist in the smaller pelvis the question of draining into the vagina rectum and extra-rectal drainage are to be considered.

In the catarrhal appendicitis in which no complicating peritonitis exists, this care in drainage is not necessary. Such cases are best treated when closed immediately. Parker's operation is to be used only when pus is obtained close to the abdominal wall and near the anterior superior spine. It is a method which will be of great use and attended with very slight danger, but will only be advisable in the older cases.

I must acknowledge my thanks to Dr. Charles McBurney, who has allowed me to make use of these cases.

7 West Thirty-first Street.

THE FORMS OF CEREBRAL HEMORRHAGE.[1]

By CHARLES L. DANA, M.D.,

NEW YORK.

I. **Ingravescent or Progressive Apoplexy, with Comments on the Question of Surgical Treatment.**—There are three sets of intra-cranial blood-vessels, those in the dura mater, those in the pia mater, and those in the substance of the brain. We have correspondingly three types of intra-cranial hemorrhage: the dural, or pachymeningeal, the pial or subarachnoid, and the central (including cerebellar and pons hemorrhages).

The central hemorrhages are far the most common, and present a tolerably uniform clinical type.

There is one form, however, which seems to have escaped critical attention, though it cannot be excessively rare. It is of this I wish to speak first.

In 1876 Dr. Broadbent reported six cases[2] of what he termed "ingravescent apoplexy." It was a form of apoplexy characterized in its onset by sudden headache, vertigo, sometimes vomiting, but without loss of consciousness. Complete hemiplegia, with hemianæsthesia, rapidly sets in. The patient becomes somnolent, stupid, and finally comatose. Death invariably occurs at the end of from one to five days, with characteristic respiratory disturbances and rise of temperature. The clinical features of this type, as described by Dr. Broadbent, were its onset without loss of consciousness, the hemiplegia, with anæsthesia, the steadily progressive course, and fatal termination.

After death the hemorrhage was found to involve the white matter posterior to the outer segment of the lenticular nucleus, and to cleave its way forward into the external capsule. It involved the internal capsule in its more posterior part, and it finally broke into the lateral ventricle. The vessel affected in these cases is evidently one of the posterior branches of the external lenticular artery.

In *Le Progrès Médical* for April 27, 1889, M. P. Puesch, of Montpellier, reports a case of this character, and analyzes it in connection with the cases previously reported.

Dr. Charles K. Mills, of Philadelphia, has reported cases of this character. A very typical illustration of it is given in a paper read by Dr. J. A. McBride, by title, before the American Neurological Association, at its last annual meeting.

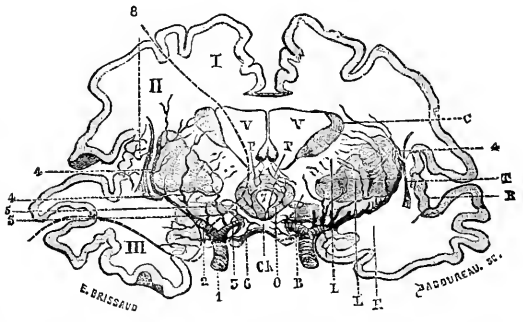

Fig. 1.—Vertical Section of Cerebrum at Level of Anterior Border of Præcentral Convolution, showing clot cleaving through external capsule.

I have met two cases presenting the general clinical characters of ingravescent apoplexy, but was able to make an autopsy upon only one, of which the history is as follows:

A woman, aged thirty-four, was brought to the hospital May 1st, without any history. She was in a stupid condition but not unconscious, and she was at first thought to be intoxicated. Examination showed, however, some hemianalgesia of the left side, and slight hemiplegia of this side. The right pupil was slightly contracted, temperature normal, pulse tense. Next day the patient's mind was slightly clearer; she answered questions and recognized those about her. But her hemiplegia was very much worse, and her analgesia no better. Toward night she became more stupid, and finally comatose; œdema of the lungs developed. No contractures of the paralyzed side were noted. The temperature rose. She died the next day, May 3d. At the autopsy the brain was found congested. Pressure over the left supra-marginal gyrus showed that there was a softened place beneath it. The brain was placed in boroglycerine and alcohol, and opened later by vertical sections. These showed a clot in the left lateral ventricle and some blood in the third ventricle. Beneath the supra-marginal gyrus was a large hemorrhagic focus about an inch and a half in diameter. This extended forward and downward, cleaving the external capsule. The hemorrhage had finally extended down and inward, and broken into the lateral ventricle, as shown in the cuts.

[1] Read at a meeting of the Northwestern Medical and Surgical Society, March, 1890.

[2] The Lancet, London, 1876, p. 887.

Comments.—Puesch has attempted, on the slender basis of seven cases, to erect "ingravescent," or, as he calls it, "progressive," apoplexy into a distinct type. This seems to me somewhat premature. The history of my case is not exactly like those of Broadbent's in respect to retention of consciousness; and the hemiplegia was relatively less marked. Yet anatomically it was one of the "cleaving" hemorrhages due to rupture of a posterior branch of a lenticular artery, and running the same course as was described by Broadbent. The hemianæsthesia seems to me to be a very distinctive point.

Practically the question comes up whether in such cases trephining would be justifiable. In general, the idea of trephining for non-traumatic hemorrhage is not to be entertained at all. But in ingravescent apoplexy it deserves consideration because the hemorrhage here is accessible, and because, unless some relief is given, it will surely break into the lateral ventricle and kill the patient. In all the reported cases, also, the patients are not old—not above fifty years of age—are not syphilitic, and presumably have not extensively diseased arteries.

In my own case, if the original focus of the disease had been reached on the first or second day, it is most unlikely that the hemorrhage could have torn its way into the lateral ventricle.

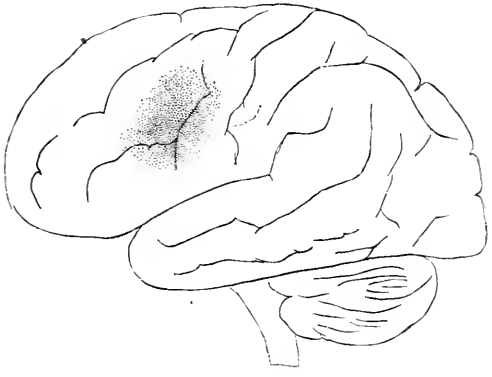

FIG. 2.—Section at Level of Posterior Border of Postcentral Convolution, showing original site of clot.

In reaching hemorrhages in these cases, the best place to trephine would be a little below and in front of the parietal eminence. The surgeon should then explore downward and forward, remembering that he must not injure the terminal branches of the Sylvian artery, which are in this neighborhood. The needle or probe may be plunged into the brain for from one and one-half to two and one-third inches.

To reach the internal capsule in its anterior or middle parts, the common seat of cerebral hemorrhage, a different route must be selected. From some experiments on the cadaver, I should recommend that a point be found midway between the anterior and posterior ends of the corpus striatum and optic thalamus, respectively (*vide* Rule X. in my rules for cranio-cerebral topography). Trephine here at a point one and a half inch from the median line. Plunge the needle directly down for one and a half to two and one-third inches. The ganglia lie about one and a half inch below the superior convex surface of the brain.

In cases of "ingravescent" apoplexy, surgical interference, if undertaken, must be before the blood breaks into the ventricles. This can be told by the sudden increase in the severity of the symptoms, and if the blood is poured in rapidly by contractures on the paralyzed side. In "ingravescent apoplexy," however, the rule is, contractures are not usually noted, probably because the rupture into the ventricle is a small one and the blood passes into it slowly. The temperature changes are believed to be the same in the ingravescent as in ordinary apoplexy, but unfortunately no complete records are given. It is most important that the temperature in these cases be taken in each axilla, and not in the rectum alone.

I trust that my imperfectly reported case may excite the interest of others, and call attention to this apparently distinctive and fatal form of cerebral hemorrhage.

II. Hemorrhage from the Vessels of the Dura Mater—Hæmatoma of the Dura Mater—Pachymeningitis Hæmorrhagica.—Injuries furnish the most of the hemorrhages of the dura mater; but idiopathic hemorrhage is by no means rare, and it seems to be especially common in American cities. English writers on neurology speak of pachymeningitis hæmorrhagica as little more than a pathological curiosity.

The symptoms are so variable that a much further study of the cases is needed, and this is my excuse for collecting here some of those which have come under my observation.

The two great predisposing causes of apoplexy of the dura mater are chronic alcoholism and chronic forms of insanity. The disease has been brought on experimentally in dogs, by giving them excessive amounts of alcohol. (Leyden.)

The older view of the pathology of these hemorrhages was that there was first an internal pachymeningitis, and then a breaking of blood-vessels in the new-growth. The later view of Sperling and Huguenin is now more widely received. It is that the hemorrhage occurs first; that then the clot becomes organized and a membrane formed. The blood-vessels here are numerous and frail. They break, and fresh hemorrhage with the formation of a new membrane occurs.

Such is, in my opinion, undoubtedly the true pathology of most of these cases.

Pachymeningitis hæmorrhagica, so called, is, as a rule, not a meningitis, or a true inflammatory process, but primarily an apoplexy of the dura mater from bursting of one of its diseased vessels, usually some branch of the middle meningeal.

The amount of blood effused may be from one or two to seven or eight ounces.

Histories of Cases.—I have the records of seven cases with autopsies. Some of them have been reported in brief in connection with the presentation of the specimens.

CASE I.—Woman, aged thirty, of alcoholic habits, admitted to hospital in a stupid condition, with paralysis of left side of face and arms, normal temperature. She became partially comatose, and had several convulsions limited to the face and arms, more on the left side. No anæsthesia could be noted. The eyes would open and shut rapidly during convulsions. The pupils were at first normal, but later were evenly contracted. Patient developed fever, became comatose, and died on the second day of pulmonary œdema. Autopsy showed a large surface clot on the right side of the brain, causing the most pressure on the lower and posterior part of the post-central convolution. In the right posterior fossa a false membrane could be peeled off from the surface of the dura mater.

CASE II.—Woman, aged fifty, of alcoholic history. She had suffered a long time from frontal headache. She had been semi comatose for three days when admitted, and she remained so for the succeeding twenty-four hours in hospital. She showed no distinct signs of paralysis, but both her arms were rigid and her legs slightly so. She died of exhaustion.

Autopsy.—Dura mater not abnormally adherent to bone. On inner surface of dura mater, on right side, was a large hæmatoma, covering the anterior and middle lobes, flattening and narrowing the convolutions of that side, and flattening and widening those of the opposite side. The innermost part of the clot was still in a semi-fluid state. External to this was an older coagulum, and be-

neath the latter was a fully organized false membrane, evidently quite old, which, under the microscope, showed fully formed connective-tissue elements and thin-walled blood-vessels. The arachnoid and pia mater were normal. The spinal cord was normal, with the exception of a few small calcareous plates found in the arachnoid of the lower part of the cord. Other organs normal.

CASE III.—That of a woman, whose brain was shown before the Practitioners' Society last fall. The patient, aged fifty, was a chronic alcoholic, and entered the Bellevue Hospital in a state of alcoholism. Although she had not taken any liquor for several days, yet she lay in the state which usually characterized chronic alcoholics. She was stupid, and partially unconscious at times, and occasionally showed muttering delirium. She took food with difficulty, answered only a few questions, had no special fever. She continued this way about a week, and died of symptoms of pulmonary œdema and exhaustion. There was no sign of paralysis at any time. At the post-mortem he found a very typical form of pachymeningitis hæmorrhagica affecting the convexity of the right hemisphere. The dura showed at least four different fibrinous layers, indicating that there had been, at different times, as many as four effusions of blood with organization of the clot. The symptoms had resembled very much those of so-called wet brain, or œdematous brain. That had been his diagnosis, with, perhaps, a low grade of meningitis such as characterized alcoholism.

CASE IV.—A woman, aged sixty-eight, who suffered from right hemiplegia and hemianæsthesia, aphasia, and convulsions limited to right arm and face. On post mortem examination there was found a large fresh dural hemorrhage pressing on the upper half of the central convolutions, and extending more posteriorly.[1]

CASE V.—Woman, aged thirty; Canadian. Patient has been a moderate drinker of beer and whiskey; no history of syphilis is given. In past two years she has had several pulmonary hemorrhages, and two weeks before admission she developed decided signs of phthisis. She also suffered intensely from headache. Patient, on admission, was obliged to go to bed. For the first few days was very restless, and almost in constant motion from the cephalalgia and pain along the spine; as time passed she became more quiet, and lying with closed eyes, seemed to sleep a large part of the time. There was incontinence of urine and constipation. For the last two days her mother has noticed muscular twitching in the arms. No rigidity of the neck was observed. She has been gradually getting worse, the stupor has been increasing, and it has been very difficult to get her to take nourishment.

Physical Examination.—Both feet are latero-inverted, and the toes inverted. There is an absence of all reflexes. The knees are not rigid, but are reflexed and rest on the right side of the bed. There is some right facial paralysis, and the mouth is drawn to the right side. The pupils are contracted, but respond slowly and irregularly to light. There is no photophobia. The pupillary orifice is irregular and more oval than round. There is marked rigidity of the neck. There is incontinence of urine and constipation. At the apex of the right lung there are a few crepitant râles, and all over the rest of the lung there are a few subcrepitant râles. Otherwise the lungs are normal. The heart is normal. Urine, acid, specific gravity 1.030, amber, no sugar, no albumin. Micro-leucocytes, round and polygonal cells. Sediment, mucous. Two days after admission she died.

Autopsy.—Between the dura mater and the pia mater, over the posterior superior surface of the cerebrum, was a very extensive hemorrhage found. Underneath the position of the hemorrhage, the convolutions were considerably compressed. There was some congestion, but otherwise the brain appeared normal. The vessel from which the hemorrhage occurred was not ascertained with certainty, but it was supposed to come from one of the middle meningeal arteries. The spinal cord was not examined. The heart was normal. The lungs were bound down to a certain extent by old adhesions. Both lungs were congested, and in the lower lobes a considerable œdema was found. The liver was somewhat diminished in size, but did not seem especially firm. No other abnormal change was observed. The spleen was somewhat soft, but otherwise normal. Both kidneys were firm, but diminished in size, the capsules somewhat adherent, and the markings were quite indistinct, and many of them obliterated.

Distinctive Symptoms and Diagnosis.—The principal symptoms in the foregoing cases were headache, stupor, and coma; convulsions which were not general, restlessness and delirium, paralysis of hemiplegic type, usually not very profound.

In one case, rigidity.

The onset is not very sharp, as a rule. The temperature is not much affected, except by complications.

There was a curious predominance of the female sex, and the age of the patients was not an advanced one. Cases are reported of large dural hemorrhages without symptoms, but these almost always occur in the insane.

In alcoholic cases some evidence of the trouble is shown, unless the hemorrhage is slight.

It must be remembered, finally, that profound alcoholism may greatly obscure the symptoms.

III. Hemorrhage in the Cerebral Cortex—Pial Hemorrhage.—This is a form of hemorrhage which is not so extremely rare. The most frequent causes are trauma and alcoholism. Insanity and syphilis also take prominent part in the etiology. Blows on the head of the chronic alcoholic seem to cause sometimes a dural hemorrhage. The hemorrhages are usually small; but they not infrequently are multiple. The symptoms may be very slight if the lesion is not in the motor area. If it is here partial convulsions and paralyses may occur.

The pathology of cortical hemorrhages is like that of central hemorrhages, *i.e.*, arterial disease, miliary aneurisms, and rupture.

The writer excludes from consideration that special class of meningeal hemorrhages which occur in the newborn.

The following case is instructive, both from the point of cerebral localization and cerebral surgery.

George K——, aged fifty, English, a tinsmith by trade, was admitted to Bellevue Hospital July 8th, in a comatose condition. He was reported to have been picked up in the street unconscious, and to have had six convulsions before he reached the ward. No further history could be obtained. His head bore the marks of some extensive scalp wounds recently healed, and of an old and small fracture, on the right parietal bone. The thoracic viscera were normal, and there was no albumin in the urine.

Every five or ten minutes the patient would have a convulsion lasting about a minute. The spasms, which were mainly clonic, began in, and were confined to, the right face, head, and arm. The head was turned to the right, the eyes deviated to the right, the arm was half raised, the forearm about half flexed, and the hand half closed. The flexors were, therefore, predominantly affected. After the convulsion ceased the patient lay quiet and almost unconscious. There was, however, an evident paresis of the right side. It was impossible to say whether or not there was anæsthesia. The pupils were rather small, no reflexes could be elicited. I diagnosticated a cortical hemorrhage of the left hemisphere, pressing on the arm and face centres. The old fracture was on the right side and not over any motor region, and I could not attach any direct importance to it. Despite all treatment the convulsions continued, and the patient was finally transferred to the surgical side for operation. It being then mid night, the house-surgeon, Dr. Biggs, was obliged to operate. The patient was too much exhausted to rally, and he died a few hours later.

[1] MEDICAL RECORD, March 5, 1887.

The autopsy showed a small diffuse sub pial hemorrhage, not more than a drachm in amount, lying in the position indicated, *i.e.*, at the base of the second frontal, extending into the lower half of the præcentral and into the base of the third frontal.

There was no other lesion of the brain whatever, though the arteries at the base were somewhat thickened and atheromatous. The kidneys showed some chronic diffuse nephritis. The other organs were normal.

The hemorrhage infiltrated the cortical tissue, and I presume that on this account, though small, it was sufficient to cause extravasation from the convolutions.

Principal Symptoms and Diagnosis.—A history of alcoholism, syphilis, or insanity, or of trauma, may lead to the suspicion of cortical hemorrhage. The small amount or absence of paralysis, and of extensive anæsthesia, the decided limitation of the convulsion, and the absence of continuous stupor or coma, lead to the suspicion of cortical rather than dural hemorrhage. The diagnosis cannot, however, as yet be positively made.

Alcohol plays a much more important part in causing cortical and dural hemorrhages, while syphilis attacks the basal and central vessels. Bright's disease, cardiac disease, and the various agencies which bring about chronic endarteritis, show their effects in central hemorrhages. These facts must be borne in mind when the question of diagnosis arises.

In a second case, the patient, a man thirty-seven years of age, was brought to the cells in a stuporous condition, and showing the evidences of chronic alcoholism. He lay in a semi-comatose condition, not speaking or showing signs of intelligence, for six or seven days. He showed evidences of slight left hemiplegia, he had no convulsion. He finally died of exhaustion.

On autopsy, a hemorrhage in the cortex was found, involving the right upper parietal and part of the central convolutions.

A few small purulent foci were found in the kidneys.

To recapitulate: Of the three forms of cerebral hemorrhage—dural, cortical, and subcortical or ganglionic—dural hemorrhage is most apt to occur in women, in the insane, and in alcoholic subjects, between the ages of thirty-five and fifty years. The main symptoms are headache, delirium followed by stupor and coma, localized convulsions, and often some paralysis. Cortical or pial hemorrhage is distinguished, when it causes symptoms, by a stricter limitation of the convulsions and the paresis. The ingravescent form of central hemorrhage is also most frequent among women, and the lesion is most common upon the right side. The symptoms are pain, vertigo, vomiting, retention of consciousness at first, hemiplegia and anæsthesia, the symptoms being progressive and surely becoming fatal. In the cases thus far reported, the lesion has been in the external capsule, between the lenticular nucleus and the cortex.

Alcohol, insanity, and trauma affect the cortical and dural vessels.

Syphilis, chronic Bright's disease with its endarterites, cardiac hypertrophy, affect the basal and central vessels.

The Phenylhydrazin Test for Glucose.—This method is based on the power of phenylhydrazine to unite with grape-sugar and form characteristic crystals. To a measuring beaker half full of water, two drachms of hydrochloric phenylhydrazin and three of sodium acetate are added; the compound having been heated a little, the same quantity of urine is added, and the beaker placed in a vessel of boiling water for fifteen minutes; it is then quickly put into very cold water. After standing for some minutes a yellow sediment slowly falls, in which crystals of phenylglucosazon are always to be found if the least quantity of grape-sugar be present in the urine. These yellow crystals have the shape of long rods, terminating at each end in round balls or bunches.

THE STERILIZATION OF CATGUT, WITH A DESCRIPTION OF A NEW, SIMPLE, AND EFFICIENT METHOD.

BY GEORGE R. FOWLER, M.D.,

SURGEON TO ST. MARY'S HOSPITAL AND THE METHODIST EPISCOPAL HOSPITAL, BROOKLYN, N. Y.

FOR a long time the writer has been impressed with the utter unreliability of the catgut as ordinarily furnished to the profession by the manufacturers, and the extreme difficulty of perfectly sterilizing this substance, in the meshes of which are to be found an almost constant proportion of fatty matter, the presence of which will successfully resist the very best directed efforts heretofore known to bring potent germicides in contact with the minute interstices of its structure. It has been suggested that treating the gut with juniper-oil and ether would be efficient in removing this fatty matter; but in the experience of the writer, catgut thus treated has seemed to contain quite as much fat and oil as a sample of the same before being so treated. If any doubt as to this exists, let a glass spool of catgut prepared in carbolized oil, such as is furnished by any purveyor of this class of goods, be placed in juniper-oil and then washed in ether. A sample of such an oil-soaked material will be found, if continuously immersed in ether for three months, to contain about the same amount of oil and fatty matter as before.

No argument on my part is necessary to convince those who have given any thought to the subject, that in the catgut of commerce, produced as it is in large quantities, and prepared by those who possess in but a slight degree a knowledge of the rigid precautions necessary to obtain typically aseptic wound-healing, and in whom there is but slight reason to expect the exercise of that care so essential in its preparation, sources of danger not readily appreciable, but none the less present, exist. Kocher, of Berne,[1] has related an experience which might be duplicated again and again by other surgeons. This surgeon noted that a series of cases of interrupted wound-healing pursued a course so uniform as to suggest a common source of infection. A revision of all antiseptic apparatus and dressing followed, and yet no improvement took place, and then the question was narrowed down to the catgut used in the clinic. Finally this was discarded entirely from use, and the former aseptic course of cases operated upon in this hospital was at once restored. Silk was substituted for the catgut on account of the greater ease with which it could be sterilized, from the fact that it is possible to employ heat in the case of this material. The greater certainty of this as a means of sterilization, and the immunity from danger when the sole reliance was not placed upon chemical germicides, were demonstrated by the behavior of wounds following this amendment to the former methods employed. Kocher's experience led him to discard catgut altogether from use in his clinic. The experience of the late lamented Volkmann at the Halle clinic, in a case of anthrax infection produced through catgut, is likewise still fresh in the surgical mind, and needs only to be mentioned to bring a feeling of dread and uncertainty to the surgeon as he reflects upon the various channels and hands through which catgut must pass ere it reaches its final resting-place in the tissues of his patient.

I have always held that catgut is the very best material thus far employed for the purposes of the surgeon, and, notwithstanding the unfavorable experience of Kocher and Volkmann, I have never despaired of being able to still avail myself of its advantages, through the discovery of some simple and efficient method of sterilization.

In the early part of the present year I was led to make some investigation upon the best methods of accomplishing perfect sterilization of catgut. I succeeded, after trial of several methods—always keeping in mind the fact that heat must enter as a prominent factor into the method which

[1] Correspondenzblatt f. Schweizer Aerzte, 1888.

was to be finally chosen, as well as the equally important fact that the thermal death-point of the graver forms of bacillus and spores was far above that which catgut would ordinarily bear without disintegration—in developing a plan of procedure which, after practical trial as well as experimental study, has thus far proven thoroughly effectual, and at the same time possesses the advantage of simplicity. The method consists simply in boiling the catgut of commerce for one hour in ninety-seven per cent. alcohol, the boiling-point of which is 183° F. Under this treatment the gut ceased to produce infection, which had previously been a frequent cause of an interruption of the healing process in a number of instances, in spite of my best care; in addition to the advantage thus gained, it was found that the tensile strength was increased, and the tendency of the strands to slip through the hands while tying, and the knots themselves to become loosened from the same cause (slipping), was markedly lessened. As for the behavior of the catgut in the tissues, there seems to be but slight change effected in its structure, so far as its absorbability is concerned. I have thought that sutures held somewhat longer after this method of preparation than in the case of catgut prepared after other methods, with the exception of the chromic gut of Lister. This is rather an advantage than otherwise, particularly in trachelorrhaphy and perineorrhaphy cases.

Following these observations, I requested Dr. Eugene Hodenpyl, of the Bacteriological Laboratory of the College of Physicians and Surgeons, New York, and Pathologist to the Methodist Episcopal Hospital, to make a series of experiments to demonstrate whether or not the method of disinfection by boiling in alcohol would bear the test of infection and culture experiment in vogue among bacteriologists of the present day. In response to my request, Dr. Hodenpyl conducted a series of experiments and reported as follows:

1. Bits of unsterilized catgut, when planted in various sterilized culture media, caused a number of colonies of bacteria to develop in all instances. The species of growth was not determined.

2. Bits of catgut, boiled for five minutes in alcohol ninety-seven per cent. and afterward dried, and then planted in culture media, remained sterile in most instances. In two of the culture-tubes of this series a bacterial growth developed.

3. Bits of catgut, which had been boiled in alcohol for one hour, were dried and planted in culture-tubes. In all cases the tubes remained sterile.

4. Small pieces of catgut were soaked for twenty-four hours in active beef-tea cultures of: *a*. Streptococcus pyogenes; *b*. Staphylococcus pyogenes aureus; *c*, Anthrax bacilli; *d*. Anthrax (spores).

The catgut was afterward boiled in strong alcohol for different periods of time, and after being dried, was planted in culture media.

After fifteen minutes boiling, sterilization was not complete, as some of the tubes showed a bacterial growth. After thirty minutes all the culture-tubes remained sterile, except those which were planted with catgut which had been impregnated with the spores of anthrax. After forty-five minutes, and one hour, sterilization was complete.

Conclusion: Catgut ligatures may be completely sterilized by boiling them for one hour in strong alcohol.

Since bacteria are not capable of development in strong alcohol, the sterilized ligatures may be kept indefinitely in this fluid.

As to the steps of the method of preparation itself, but little need be said. I have found however, practically, that a pint of the alcohol is sufficient for sterilizing fifty metres of the catgut. The latter is wound upon the ordinary small wooden spools used for winding cotton and linen thread, these being previously boiled in a solution of soda for a time in order to cleanse them, and at the same time remove any coloring matter. The catgut, thus wound upon spools, is placed in a small fruit-jar, or ground glass stoppered bottle, the cover or stopper being left loose or removed, and the requisite amount of alcohol poured over it. This is then placed in a water-bath or one of the steam milk sterilizers, in common use, or any method of boiling the alcohol may be employed. Should there be a suspicion that the gut has become reinfected by handling or exposure, it may be resterilized by again boiling it, without impairing its texture.

I am well aware that the best culture medium is the fluids of the animal body itself, and that these experiments can be carried still further by a study of the behavior of catgut previously infected, and then presumably disinfected in these tissues. This I propose to do at an early day, but the culture experiments already made, as well as my own experience in actual practice, show that this method possesses advantages which appeal to the mind of the practical, hard-working, every-day surgeon. My first specimens of disinfected catgut were treated by being boiled in the ninety-five per cent. alcohol of the shops, and this served me well, but in view of the possibility of this product being still further diluted with water, which would tend to destroy the gut, the ninety-seven per cent. alcohol is more to be relied upon.

Progress of Medical Science.

Observations on the Microbe of Diphtheria.—Dr. Klein has published an account of his researches concerning the transmission of diphtheria by means of the Klebs-Löffler bacillus. While this disease, which caused the deaths of more than 38,000 persons in this country in the census year 1880, is easily communicated from one human being to another, there have been many epidemics in which the origin of the infection could not be clearly shown. The result of Dr. Klein's experiments may throw light on cases that have baffled ordinary inquiry. In human diphtheria the bacilli are found only in the diphtheritic membrane, and it is believed by many that the disease is caused by a poison excreted by these minute organisms at that place and absorbed into the system. Dr. Klein found that when guinea-pigs or cats were inoculated with the bacillus of human diphtheria the microbes were confined to the seat of inoculation, and there was caused a severe and fatal disease of the lungs. For some years the London health officers had been telling him about "a curious relation existing between a mysterious cat disease and human diphtheria in this manner; that a cat or cats were taken ill with a pulmonary disease, and while ill were nursed by children, and then these latter sickened with well marked diphtheria. Or children were taken ill with diphtheria, and either at the same time or afterward the cat or cats sickened." He says: "The disease in the cat was described as an acute lung trouble. In one instance—in the north of London, in the spring of 1889—this cat malady, occurring in a house where diphtheria soon afterward appeared among the children, was of a widespread nature; a veterinary surgeon, Mr. Daniel, informed me that at that time he had several patients among cats affected with the disease, consisting of an acute catarrhal affection, chiefly of the respiratory passages. He furnished me with two such animals; one that after an illness of several weeks had died, another that was sent to me in a highly emaciated state, affected with severe broncho pneumonia; this animal was paralyzed on the hind limbs. In both instances the post-mortem examination showed severe lung disease, broncho-pneumonia, and large white kidneys due to the fatty degeneration of the entire cortex. A similar condition is met with in the human subject in diphtheria. Further, I received from Dr. Thursfield, of Shrewsbury, the body of a cat that had died after a few days' illness from pneumonia in a house in which children were ill with diphtheria; another cat in the same house, that next became ill with the same lung trouble, also succumbed." Dr. Klein found that cats inoculated with the

bacillus of human diphtheria died in the same way—of lung disease and fatty degeneration. His conclusion was that in the cat the natural disease of diphtheria was a lung disease, and that the lung is the organ in which the diphtheritic process in the cat has its seat. Further experiments confirmed this conclusion. During the last ten or twelve years certain epidemics of diphtheria in or near London have been traced to the milk supply, but it could not be shown in what manner the milk had become contaminated. The evidence was strong that there had been no direct pollution from a case of diphtheria in a human subject. The cows were reported to be in good health. But it was admitted that two or three of them exhibited symptoms of some disease on the udder. This fact and the experiments with other animals, suggested to Dr. Klein a course of inquiry. Two milch-cows were inoculated in the shoulder with a culture of the bacillus of human diphtheria. Beginning with the fifth day, each cow exhibited on the udder an eruption like that which had been reported in the unexplained epidemics. One died on the fifteenth day, the other became very ill and was killed on the twenty-fifth day. It should be noted that the fatal disease appeared to be broncho-pneumonia, with necrotic changes in the liver, and that it really was diphtheria in the form in which this disease is manifested in a cow. The eruption on the udder continued for about seven days. The description of it recalled the descriptions of the similar disease discovered in the herds in the case of the diphtheria epidemics. But while the diphtheria bacillus in the human being, the guinea-pig, and the cat is confined to the seat of inoculation, in the cow it passes into the system. In milk taken with the greatest care from one of these cows, there were found thirty-two colonies of the diphtheria bacillus in one cubic centimetre of the fluid. The presence of the bacillus in the eruption on the udder was also demonstrated, both by microscopic examination and by experiment. Two calves inoculated from the udder exhibited the same disease near the seat of inoculation, and then became affected with "severe broncho-pneumonia and with fatty degeneration of the cortex of the kidney." The last experiment mentioned was an accidental one. At the beginning of last April two cats died at the Brown Institution—where these investigations were made—after having been ill for several days, "with symptoms like those of natural cat diphtheria." Before the end of April fourteen cats became similarly affected, and some of them died. At first Dr. Klein could not account for this. The two cats that were the first to die had been healthy when they were brought to the place. Careful inquiry, however, left no room for doubt as to the origin of the infection, and gave to this accidental experiment considerable value. In the latter half of March there were in the stables of the Brown Institution the two cows already mentioned, which were ill with diphtheria induced by inoculation with the bacillus of human diphtheria. As soon as the bacillus was found in the milk taken from these cows the attendant was directed to throw this milk away. He had disobeyed his instructions and had given some of it to the two cats, which soon became sick, and from which the disease seems to have been communicated to their fourteen companions.—*The New York Times.*

A Case of Excision of the Entire Humerus.—In the *Medical and Surgical Reporter* Dr. Sexton has described an unusual case of excision of the entire humerus. A boy, aged ten, injured his shoulder by a fall on the ice in February, 1888. Abscess followed, which pointed below the deltoid, and left a sinus leading to dead bone. The patient came under Sexton's observation four months after the accident. There was then marked bone disease up to and involving the head of the humerus. About the shoulder and half-way down the arm the structures were all infiltrated. The humerus itself seemed enlarged at the middle third, as if by callus, but there was no history of fracture. The boy's septicæmic condition and the excessive heat of the season contraindicated operation further than to excise and drain tissues near the joint. His general health improved upon tonics until October 1st, when twitching and jerking movements of the hand and arm were noticed. These movements became more violent and painful, and by the 29th had involved almost every movable part of the body in a severe chorea. The face wore an expression of imbecility, and the patient was rapidly sinking from exhaustion. After consultation it was decided to operate, with the idea that not much good would be likely to result from treating the chorea—whether reflex or otherwise—with the arm in its present condition. With the intention of excising the head and as much of the shaft as might be diseased, a downward incision, six inches in length, was made from the tip of the acromion. The head of the bone was thrust out of the wound, and the shaft sawn through about its middle. The bone below that point was evidently diseased, so that the incision was prolonged to the radial condyle, the elbow-joint opened, and the entire humerus removed. The wound healed well under antiseptic treatment. The chorea ceased, of course, under the anæsthetic, and returned about three hours after the patient's awaking, but not violently, nor did it cause any pain. Ten days afterward the chorea was well, and in thirty days the boy began to use his arm. Four months after the operation the report showed perfect health; no chorea; wound united; no signs of bone growth. Measurement gave two inches of shortening to the affected arm, with greater circumference than on sound side; motion of fingers perfect; "can lift to a good advantage," and carry a burden; can dress himself; no muscular atrophy. The author observes that he cannot find a single recorded instance of grave operation in the presence of chorea. Many minor operations, such as removal of foreign bodies or division of nerves, are reported. He is inclined to trace the disease rather to the debility consequent on long-continued suppuration than to reflex irritation. On the other hand, the history of the case undoubtedly follows the rules supposed to demonstrate reflex chorea. It began in, and was confined to, the arm; and it must be confessed that the anæsthetic, the shock of operation, and the removal of local disease, exerted a promptly curative effect upon the nervous phenomena. The operation of excision of the entire humerus is rare. This probably results from the fact that—1. Any lesion calling for removal of the entire bone generally comes within indications for amputation at the shoulder-joint. 2. Mortality after amputation is less after excision of the head with any considerable part of the shaft of the bone. 3. Because it has been held that a flail-like arm is of no use whatever, and rather an encumbrance than otherwise. On the other hand, it may be urged that there may be bony regeneration of considerable amount; that the preservation of the outline and form of the member is more sightly than an empty sleeve; that, on account of the shortening, thickening, and consequent strengthening of the muscular tissues, no little degree of leverage will be preserved, and much valuable power of fingers, hand, and wrist, be retained.

Infection by Typhoid Bacilli without Intestinal Lesions.—Dr. Vaillard recently communicated to the Société des Hôpitaux a case of infectious disease in which he discovered the presence of the typhoid bacillus and the streptococcus without there being any intestinal lesions. A young soldier, convalescent from slight grip, presents successively headache, great lumbar pains, cerebral excitation, with a high temperature and abundant epistaxis. There soon followed coma vigil, with complete anæsthesia, contraction of the nape of the neck and of the muscles of the pharynx, and obstinate constipation. Death occurred on the tenth day, after a brief warning of cerebral symptoms. The autopsy revealed general congestion and localized œdema of the cerebral and spinal meninges. The lungs were congested; the spleen,

swollen and softened, weighed ten ounces. There was no alteration of the intestine. Cultures on different media were made with the splenic pulp, blood from the lungs, and parts of the spinal marrow. They revealed a bacillus, morphologically like the typhoid bacillus described by Eberth, Gaffky, Chantemesse, and Widal. Besides, there was found in the spleen and the meningeal exudate the streptococcus which has been described as occurring in cases of fatal grip. The patient, therefore, succumbed to a mixed infection of the streptococcus and of the typhoid bacillus. M. Vaillard claims that typhoid fever has in this case run its course without its usual train of symptoms and lesions. Why should not typhoid infection be able to exist without manifesting the intestinal signs and localizations described by Louis and his successors? Banti has observed a case of typhoid fever without appreciable intestinal lesions, but in which the typhoid bacillus was found in the spleen and mesenteric ganglia. Adinot cites a case of meningitis without intestinal alteration, in which the meningeal exudate contained a bacillus which he identified (though without positive proof) as being the typhoid bacillus. Vaillard thinks, therefore, that in certain cases the typhoid bacillus may cause a fatal infection without producing the lesions characterized as pathognomonic of typhoid fever.—*The Weekly Medical Review.*

The Transmission of Typhoid Fever by the Air.—The principal characteristic of contemporary medical science is the attempt, which in many cases has been largely realized, to determine the mode of propagation of infectious diseases. Although much still remains to be accomplished, yet immense progress has been realized in this direction, and it is hardly necessary to say that when these questions in etiology receive their solution prophylaxis will at the same time be greatly advanced. In the case of typhoid fever, as yet, but one mode of explaining the spread of this disease is recognized, and that is through the mediation of water, or of drinks accidentally charged with typhoid discharges. But the question as to whether water is the sole vehicle for the typhoid bacillus can only be answered by the recognition of the bacillus in the air, and by the establishment by clinical observation that typhoid infection may occur through the pulmonary passages. Recently Dr. Bordas has undertaken a series of researches which appear to show that the bacillus of typhoid fever should be classed among the aërobic micro-organisms. He has recognized that this bacillus remains inactive in dry air completely deprived of vapor, and that it continues to live, and even to multiply, in an atmosphere more or less charged with humidity. This last explanation is especially important, as offering an explanation of certain peculiarities which have as yet escaped satisfactory explanation; such, for example, as the great frequency of typhoid fever in October and November, months which are ordinarily accompanied by the greatest atmospheric humidity. The experience of Dr. Bordas further shows that the contagion of typhoid fever may be for a long time preserved in its activity, and that the explanation of this is largely found in the fact that the periods of prolonged dryness, which are the cause of destruction for the bacilli, are relatively rare. Finally, there is nothing impossible in the belief that the bacillus is capable of directly penetrating into the respiratory passages, and thus starting the typhoid infection.—*The Therapeutic Gazette.*

Recent Observations on the Action of Caffeine.—In an article concerning the properties of caffeine, by Dr. Reichert (*The Therapeutic Gazette*), we are informed that coffee and its two conceded active principles—caffeine and the oil of coffee—are generally believed to act as stimulants to the circulation, increasing the force and frequency of the pulse and the amount of work performed by the heart; yet the evidence upon which this is founded is far from convincing, there being but few cases of poisoning on record, the actions of therapeutic doses having been but little studied, and the results of experiments on the lower animals insufficient and conflicting. From the author's personally conducted experiments he concludes the following: 1. The pulse-rate may be diminished during the first and last stages of caffeine poisoning, but is generally decidedly increased. During the first stage the diminution is due to a stimulation of the cardio inhibitory centres in the medulla oblongata and heart, and during the last stage to a direct depression of the heart. The increase in the pulse-rate is due to a depression or paralysis of the above cardio-inhibitory centres. 2. Arterial pressure during the first stages of poisoning is generally unaffected or diminished, but occasionally a trifling increase is noted; during subsequent stages it is diminished. The increase is due to a direct stimulant action upon the blood-vessel walls, increasing vascular tension. The diminution is due chiefly to a direct depression of the heart, and to some extent, doubtless, to a secondary paralyzant action on the vessel walls. 3. The acceleration of the heart-beats may be accompanied by no appreciable alteration in blood-pressure, but generally by a more or less decided diminution, which is dependent upon cardiac depression. 4. Caffeine diminishes the heart's efficiency for work, arrests it in diastole, sometimes induces sudden paralysis, and is, therefore, a cardiac depressant. 5. The asserted stimulant action upon the circulation is doubtless subjective, and dependent upon an excitation of the cerebral centres.

In the same journal Professor Sée concludes a paper with the following *résumé*: 1. Caffeine, in small repeated doses, when given to soldiers on the march, facilitates muscular work, not by directly increasing the activity of the muscle itself, but by acting on the cerebral and cerebro-spinal system. The consequence of this double action is the diminution of the sensation of effort and the prevention of the feeling of fatigue. 2. Caffeine prevents shortness of breath and palpitation, as a consequence of severe effort. 3. Under its use individuals subjected to prolonged violent exertion acquire the characteristics of persons in perfect physical training. 4. In producing this excitation of the cerebro-spinal motor system, on which depends the increase of muscular tonicity, caffeine increases the loss of carbon by the organism, but it does not restrain the loss of nitrogen. It does not thus in reality save tissue-waste. 5. A means of preventing tissue-waste, and so preventing the effects of inanition from fasting, is absolutely impossible of realization, since such a state of affairs could only be attained by absolute inaction or immobility, a state of affairs which it is hardly necessary to state cannot exist. With caffeine, then, the direct opposite ensues—that is, although there is intense work rendered possible, it is only obtained at the expense of the organism. The animal machine can only operate at the expense of tissue-combustion, and it is precisely in facilitating this combustion that caffeine enables muscular work even during fasting. 6. Caffeine has thus not the property of replacing foods, but only replaces the tonic general excitation which the general ingestion of foods produces. If one could assume that it was the direct, immediate, instantaneous action of foods which stimulated the stomach and the nervous system, and that their alimentary value does not extend beyond this, they could be substituted by stimulants. Finally, Professor Sée maintains that the action of caffeine on the heart and blood-vessels is different from what is generally maintained, and is a much more active stimulant than is usually believed.

Midwives and Septicæmia.—A French court has recently sentenced a midwife to six months' imprisonment. She was accused of having caused, in a single month, through neglect of the necessary precautions, the death of seven women, whom she had attended in confinement. The French do these things better than we do.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, August 16, 1890.

MEDICAL EDUCATION IN THE UNITED STATES AND FOREIGN DIPLOMAS.

DR. POTTER, of San Francisco, has published a lengthy article comparing European with American medical education (*The Journal of the American Medical Association*, July 19, 1890). He says: "Any American physician who is thrown into the society of European medical men, either at home or abroad, cannot fail to become sensible of a feeling of contempt for American medical education, and persons, which pervades the European to such an extent that, polite as he may be, he is never able to wholly disguise it. This sentiment is most freely exhibited by medical immigrants to this country, by gentlemen who come here to settle after having received a foreign medical degree or diploma. Many who show it most offensively are Americans by birth, though of foreign parentage, who have been sent abroad for their medical education. If hailing from the German or Austro-Hungarian empires, the diplomas possessed by these gentlemen do not qualify them to practise medicine in the countries where they were obtained. For not one in a thousand of such medical immigrants possesses the certificate of the State examination (*Staats-Examen*) of the country in which he was educated. Although their education is not of a grade sufficiently high to admit them to practise at home, they are admitted by our liberal laws and customs to all the legal rights and professional privileges enjoyed by the most highly educated physicians of our own or any other country. In return, very many of them rarely fail to sneer at our colleges and their graduates, or to promulgate the idea that foreign medical education is so superior to ours that American graduates are not worthy of being entitled physicians.

"This spirit pervades so many foreign medical men that it becomes exceedingly offensive to us at home, and equally humiliating abroad. Especially to those who believe, with the writer, that the assumption is unjust to our professional men and schools; and that it is based upon false information and prejudiced statements which find their way every now and again into the columns of the European medical press.

"That we ourselves are to blame for this contemptuous treatment from many who are inferior to our poorest graduates, is a fact which becomes apparent after devoting but slight attention to the subject. If we would honor ourselves, and our Harvards, Bellevues, Jeffersons, etc., by demanding from the lawyers who make our laws the application of the same tests to, and restrictions upon foreign graduates, which their governments apply to our graduates, we would strike at the root of the evil, and enforce respect with a single blow. If our laws were made to provide, for example, that no diploma from a German medical school or University would be recognized by the Pennsylvania State Board of Examiners until such times as graduates of Pennsylvania medical schools received similar recognition in the German empire, we would hear the last about fraudulent American diplomas being the distinguishing feature of our system of medical education. The authorities at Berlin and Vienna would then speedily take the trouble to inform themselves in regard to the character of our different colleges, and would soon learn to distinguish between fraudulent American diplomas and true ones, as clearly as they do between fraudulent and genuine American bonds and other securities in their financial transactions.

"The recent insolent action of the authorities of the medical school at Berlin, in denying to our graduates studying there the right to the letters "M.D." after their names in the catalogue, though giving it to graduated students from other countries, ought to open the eyes of every American physician, and excite a determined spirit of retaliation, unless we have lost our manhood entirely, and are satisfied to submit to any insult from any source. The first effect should be to draw our students away from Berlin, where they have been flocking of late years for post-graduate study, which can be obtained by the English-speaking student with much more direct benefit at London or Edinburgh."

Now, all this sounds very well, and we have repeatedly pointed out that persons not considered fit to practise medicine by their own governments should not be allowed to engage in medicine here before giving better evidence of their qualifications than the mere showing of a foreign diploma, about the acquisition of which our authorities generally possess not the slightest information.

At the same time, Dr. Potter weakens the force of his arguments by pleading the baby act as follows:

"When our difficulties are taken into consideration, when it is remembered that every American State, young or old, governs its own educational matters; that the central Government has no control whatever over the practice of any profession, except in its own courts, and in its own military and naval establishments; that, as yet, we have no endowments for our medical colleges; that, under our democratic institutions, every medical sect or delusion can obtain sufficient following to secure from the politicians charters for so-called colleges, with the right to issue diplomas; that we have three distinct bodies of medical practitioners, recognized by law, viz.: the Regular, the Homœopathic, and the so called Eclectic; that every effort to secure the passage of laws to control medical practice and education is fought bitterly by two of these bodies, and by spiritualists, faith-healers, magnetic healers, Christian scientists, metaphysical healers, electro-biologists, *et hoc genus omne*; that juries in the large cities are often composed of the scum of European humanity; that such juries will not convict the most flagrant violators of medical laws; it is really a wonder that we have done as well as we have in this matter

of medical education. Only by the self-sacrificing labor of the much-abused professors in our great schools have these institutions reached the high standard which is conceded to them by all fair-minded investigators."

But the high standard here spoken of is precisely what is not conceded by foreign authorities. It is a standard which we have for years advocated, and will continue to earnestly advocate. But truth must prevail, and we might as well admit that, as now conducted, medical education in our country falls far below the ordinary European standards. With few exceptions, an American medical education, that shall in essential particulars equal the European one, is still a consummation to be wished, but by no means a *fait accompli*. Nor will the new era dawn before our medical colleges cease to be business concerns, which are run primarily for the benefit of the faculty. At present it is to the pecuniary interest of these "faculties" to attract as many pay-students as possible. This can be best accomplished by making the requirements for graduation as light as possible. A recent loudly-heralded attempt on the part of a prominent college to make even a three-year curriculum obligatory was speedily abandoned when it was found that the faculty pocket-book would severely suffer.

Almost all European schools make a five years' course obligatory, and in many cases six years are spent in study before a diploma is within reach of the candidate. It is simply silly for us to seriously pretend that we turn out our thousands of doctors every year in such shape that they are medically equal to their European confrères. At the same time, it is far from just that our country should be made the dumping-ground for professional paupers, incompetents, or scum generally. The United States return objectionable immigrants of all kinds to their respective homes. Before permitting medical immigrants to practise among our people let us demand the proofs that, in their own homes, they would be entitled to practise their profession. Those unable to supply such proof should be strictly denied the privileges granted to the possessors of American diplomas. There can be no harm in applying a little of the good old doctrine of "America for Americans" to the practise of our profession, otherwise we may yet be "ruined by Chinese cheap labor."

But as regards our institutions of medical learning, what we want just now is endowed medical schools that shall be absolutely independent in a pecuniary sense—colleges that do not have to curry favor with the callow masses of young men, who only "go into" medicine because it seems to hold out fair prospects of earning a decent living, at a minimum expenditure. Despite some painfully apparent modern tendencies in our profession, it cannot and must not be degraded to the level of a mere money-grubbing pursuit.

SEBORRHŒA AND BALDNESS.

In *Gaillard's Medical Journal* for May, 1890, Dr. George T. Jackson gives an interesting account of that very common and annoying affection, seborrhœa. This disease, while it causes little actual physical discomfort, is one which may interfere decidedly with the personal loveliness, and *propter hoc*, the mental quietude of both doctor and patient, for it disfigures the face and causes dandruff and baldness. It is well for doctors to know all that there is to be known about seborrhœa. There are, we are told, two kinds of seborrhœa, viz., the oleaginous and the dry. The oily form usually occurs most markedly upon the nose and forehead, and it shows itself unmistakably and frequently on warm nights, at social gatherings, forming a greasy coating upon the nose which the most careful powdering fails to disguise. Acne and comedones may complicate it.

But the dry form is the most common, and the one we are oftenest called upon to treat.

This most usually appears in the form of yellowish or grayish fatty plates or masses, which, when taken and rubbed between the fingers, impart a greasy feel. Upon the scalp it constitutes one form of dandruff. Here it may be general, involving the whole scalp, or it may locate itself in certain places in a more pronounced way than in others. The hair is dry, and after a time, the seborrhœa continuing, it begins to fall, and at last baldness is established.

The fact that dry seborrhœa is a cause of dandruff and baldness gives to it its special importance.

Ordinarily, this form is not accompanied with any redness or inflammation. But there is a second variety in which a varying amount of dermatitis is added to the seborrhœa. Then there will be a rim of redness about the fatty crust, and when the crust is removed from the skin, the underlying part will be seen to be red. In this variety there will be far more decided itching and burning than in the preceding variety. It is to be noted that although the skin is red, it is always dry and never infiltrated, in these respects differing from eczema.

While most authorities have held that seborrhœa is a disease of the sebaceous glands, Unna has asserted that it is in fact due to an involvement of the sweat-glands, and that seborrhœa sicca is in reality a seborrhœal eczema. This view is not yet an accepted one.

Various attempts have been made to find microbes which could be considered the cause of seborrhœa. The parasitic theory gains some plausibility from the fact that antiseptics are the best curative measures, and also from certain experiments in the inoculation of dandruff. There is enough merit in this view, also, to justify the person who does not wish to get bald prematurely in having his own brush and comb at the barber's. And it may yet be that antisepsis in the barber-shop is to be the preventive of premature loss of hair.

The treatment of seborrhœa is simple. Dr. Jackson recommends sulphur.

After the removal of the crusts by means of any oil, or grease (this should be done the first thing, whatever remedy is chosen), the sulphur is to be applied in the strength of a drachm to the ounce, either suspended in sweet oil, cotton-seed oil, or vaseline. It should be well rubbed into the scalp and the application repeated every night for one week. It is well to advise the patient to wrap his head up in a towel or to wear a nightcap. This for the benefit of the housekeeper, who will thank you for saving the pillow-cases. After one week's use of the sulphur, the head is to be washed with soap and water, and the oil, or salve, immediately reapplied. During the second week it will be sufficient to make the application every other night. Thus the treatment is to be continued,

the number of applications being reduced until they are made but once a week. By this time the disease will be cured. The patient is to be cautioned that relapses are likely to occur, and therefore it will be best for him to keep a supply of his oil, or salve, on hand, so as to attack the trouble as soon as it shows itself.

Mercurial ointments are almost equally efficient; and the Lassar treatment, which has already been described in these columns, is also said to be a good one.

BROMIDE OF GOLD IN EPILEPSY.

In 1888, Dr. Goubert, of Paris, published some observations relative to the efficacy of bromide of gold in epilepsy. He described eight cases of this intractable malady, which had been apparently cured by the internal administration of this drug. He claimed that the remedy proved effective in comparatively very small doses, not exceeding one-sixth of a grain. He also stated that the drug was free from all those unpleasant effects which so frequently interfere with the continued use of the other salts of bromine.

In the *Proceedings of the St. Petersburg Society of Psychiatrists*, a case of hysteria gravis is recorded, in which the auric salt of bromine proved highly beneficial, after many remedies had signally failed. Professor Danillo, also of St. Petersburg, has recently published a number of cases in most of which bromide of gold in doses of one-fifth of a grain, was likewise promptly efficacious in suppressing epileptic seizures. A further favorable report concerning the use of this remedy is given by Professor Rosenbach, of St. Petersburg. Bromidism was not observed by any of these physicians, even when the drug was administered continuously for a long time.

Acting on these favorable impressions, Dr. Alexander E. Shtcherbak, of Professor Mierzejewski's laboratory (*Vratch*, No. 9, 1890), has recently undertaken a fairly long course of experiments on dogs with exposed cortical motor area, the principal point being to study anti-epileptic effects of the drug in comparison with bromides of potassium and sodium. The gold salt was introduced either under the skin or into the femoral vein or into the stomach. The essential results may be condensed somewhat as follows (*The London Medical Recorder*): 1. Bromide of gold undoubtedly inhibits the cortical motor centres, and that even when administered in far lesser doses comparatively than the other bromides. 2. The most marked effects are observed when the drug is injected into veins, when even 0.005 gramme pro 1 kilogramme totally inhibits the fits. 3. Irritability of individual motor centres, as determined by the appearance of contractions in corresponding muscular groups, is depressed by bromide of gold in a but trifling degree. 4. Excitability of the white substance of the motor region remains intact. 5. The drug seems to affect mainly the tracts of communication between individual motor centres as well as between the latter and remote areas of the cerebral cortex. 6. It does not appear to possess any particular cumulative action comparatively with the other bromides. 7. Of accessory effects there are observed only vomiting (very rarely, and that solely on internal use) and some depression of pathic sensibility only on the use of larger doses, such as 0.15 gramme pro 1 kilogramme. Even prolonged administration never gives rise to unsteady gait, general depression or languor, and emaciation, all of which symptoms are observed in the case of bromide of potassium. 8. The physiological effects of bromide of gold (and their being different from those of the other bromides) cannot possibly be attributed to the proportion of bromide present therein, since the strongest of the three, bromide of gold, contains the smallest amount of bromine (55 per cent. by weight), while the weakest of them, bromide of sodium, shows the richest proportion of the element (77.7 per cent.), the potassic salt standing midway with 67.2 per cent. of bromine.

With so much testimony in favor of bromide of gold, it seems reasonable to bespeak for it a further trial by clinicians. Even if only a part of the claims made for it will be realized, we may confidently add the drug to the list of those remedies that may be used, in alternation with other salts of bromine, to subdue the many conditions associated with exaggerated cerebral activity. In true epilepsy it may be found to be at least as serviceable as most of the remedies now at our command.

THE DISPENSARY ABUSE IN OTHER LANDS.

If it is really any comfort to learn that one has company in his misery, we may perhaps pass a happy five minutes in contemplating the sorrows of our cousins across the water. They, too, are coming to appreciate the sad fact that there is too much free medical work done in the different cities, and are casting about for some means to diminish the evil that threatens their practise and their pockets. The overcrowding of the profession is becoming so apparent that even the lay press has observed it and commented upon it. A Scotch paper calls its readers' attention to the fact that there are now 28,348 registered medical practitioners in the United Kingdom, an increase during the past twelve months of 1,305. Since 1880 there has been an increase of 6,232, giving an average annual rate of over 600. This multiplication of doctors can have but one result in the opinion of our intelligent lay brother, and that is to cheapen medical services. As the ranks of the profession grow more crowded the competition must become keener, and the inevitable result of active competition is to lower prices. The writer thinks that the time is not far distant when medical advice will be as cheap as prescription paper, and he thinks it will be interesting to observe whether people are the better for the change. The *Medical Press*, commenting upon this remark, feelingly observes that medical advice is even now as cheap as, and even cheaper than, prescription paper, since a very large section of the community gets not only advice, but medicine for nothing. The profession is thus being cut in upon from two opposite sides. The Universities enrich themselves by passing men in crowds into the profession, and hospitals continue to multiply, and the means of subsistence for young practitioners is thus diminished, as the hospitals now take up the patients by which they, the juniors, in olden times lived, and were expected to live, during their professional novitiate. As a result, working-class practice has all but disappeared, except such of it as is taken up by club doctors at the princely remuneration of *2s. 6d.* per head per annum, medicine included; quackery is undoubtedly

rampant, professional degradation is manifest in the protean forms of advertising resorted to, popular lectures to women, ambulance lectures, *et hoc genus omne*. *Sauve que peut* is the slogan in the wild panic and rush for existence. Within the past few years an immense number of new hospitals have come into being, in support of which the public ear is assailed with wails under a benevolent cloak.

All this has such a home-like sound that we can hardly realize that the writer is referring to London and not to New York, and we almost expected to see mention made of the Rich Mans' Relief on Madison Avenue. The same paper in a later issue notes the fact of glaring abuse of out-patient medical relief by the Belfast Royal Hospital. The members of the Ulster Medical Society have taken the matter up, and are doing what they can to obtain an abatement of the evil. A deputation called upon the hospital authorities, and pointed out to them the fact that the out-patients had increased in a few years from 9,000 to 26,000 per annum, and they gave instances of many well-to-do, mean people who resorted to the hospital, and received medical advice and medicine at the expense of the charity.

The authorities were very civil, and kindly forbore to chastise the committee for their temerity in remonstrating with them for helping the poor, but they told them that there would be great difficulty in devising a remedy for the condition complained of. That again sounds very natural. Of course, if there should happen to be any falling off in the number of patients, the hospital would apparently be doing less good, and then the charity of the public could be less confidently appealed to. The better the report, the greater the number of patients, the greater the pride of the devoted directors, and the more substantial the contributions to carry on the noble work of pauperizing the community, and of impoverishing the medical profession.

A SIMPLE METHOD FOR ESTIMATING UREA.

In this age of diagnostic investigation, when every secretion and excretion is being made the subject of chemical examination, it is very important, unless we are to create a new specialty of chemical diagnosis, that the methods of investigation be made as simple as possible. Especially is it desirable to do away, as far as possible, with the necessity for special apparatus, which is expensive and liable to be broken. The methods also should be easy of application, for every physician cannot be an expert analytical chemist, and has not the time necessary to master the details of a long and intricate process; and if there is much liability to error in the manipulations, it would be far better for the ordinary man not to attempt them.

Drs. Heaton and Vasey, writing in the *Lancet* of May 10, 1890, describe a method of estimating urea which is simple, and, though not absolutely accurate, is still approximately correct in its results. The apparatus that is really necessary is of the simplest character. In addition to the ordinary pharmaceutical measures there are needed only a thistle-headed acid funnel, about one foot of glass tubing, and a couple of bottles. The following is an enumeration of the articles required: 1. An eight-ounce bottle is fitted with a thistle-funnel and a bent glass delivery tube, as though for the preparation of hydrogen. The lower end of the funnel should be bent upward, like a small hook, to prevent gas from passing up it. 2. A small basin or coffee cup may be used as a pneumatic trough, a four-ounce bottle being filled with water and inverted in it in such a manner that the end of the gas delivery tube can readily be brought under the mouth of the bottle. 3. A forty per cent. solution of caustic soda.

The analytical process, as described by the authors, is as follows: "1. Into the gas generator is poured by means of the funnel one fluid drachm of bromine washed in by ten fluid drachms of the soda solution. The generator may then be immersed in cold water, and the inverted bottle of water placed over the end of the delivery tube. 2. Two fluid drachms of urine, very carefully measured, are added and washed in by exactly one fluid drachm of water. The three fluid drachms so added will of course cause an equal volume of air to pass into the receiving bottle. This is allowed for in the appended table. The generator is gently shaken; brisk effervescence takes place, and gas equal in volume to the liberated nitrogen is collected in the receiver. The generator should be kept as nearly as possible at the temperature of the air. 3. When the evolution of gas ceases, the receiver is removed from the basin by means of the thumb or a glass plate, and placed mouth upward on the table. It is now only necessary to measure in minims the quantity of water required to fill it. After deducting 180 (which may be taken as 200) minims due to the air displaced by the urine, each 100 minims of water added represent 0.25 per cent. of urea in the urine examined. If the urine contains more than three per cent. of urea, it is best to dilute it with an equal volume of water before making the determination."

The volume of gas liberated varies in proportion to the amount of urea present, and the former is, of course, determined by the quantity of water required to fill the bottle. The following table may be used to estimate the percentage of urea from the amount of water which is necessary to refill the bottle:

Minims of water required.	Percentage of urea.	Minims of water required.	Percentage of urea.
200	0.00	900	1.75
300	0.25	1,000	2.00
400	0.50	1,100	2.25
500	0.75	1,200	2.50
600	1.00	1,300	2.75
700	1.25	1,400	3.00
800	1.50		

Notes on Naphthalin.—Naphthalin may affect the eyes in an extraordinary manner, as asserted by Dr. Kolinski, through its property of deleteriously affecting the nutritive property of blood. The eye being a highly vascular organ, its structure readily undergoes degeneration. The effects of the administration of naphthalin are ecchymosis, white patches in the retina, cloudiness in the lens, and crystals in the vitreous humor. In a Moscow weekly, Dr. Jmüdzinovitch, of Kopal, most emphatically recommends the internal use of naphthalin in cases of cholera nostras. The remedy should be given in the dose of 2½ grains every half-hour, in the form of powders with sugar. Vomiting, cyanosis, general convulsions, etc., are said to quickly disappear, even in cases where all ordinary means have proved totally useless.

News of the Week.

Mercurial Inunction and Tape-worm.—Dr. L. Oelkers reports the case of a syphilitic treated by mercurial inunction. A tape-worm passed by him contained mercury in large quantities.

The Odor of Ichthyol may be disguised by oil of citronella. The oil is employed in Ceylon against rheumatism.

A University for Toulouse has been proposed, and the preliminaries of its establishment are said to be well under way.

The Antifebrin Habit.— Dr. Suttle, of Corsicana, Tex., reports a case where a patient acquired a habit of taking antifebrin, which presented much of the mental symptoms of ordinary habits. The physical results closely resembled those produced by the chloral habit.

Death of Dr. Frank H. McDonald.—Dr. Frank Hewitt McDonald, a widely-known and highly esteemed physician of Harlem, died at his residence on Saturday, August 2d, aged forty-seven. Deceased was born in the north of Ireland, and graduated as a physician at the University of New York. Ten years ago he came to Harlem, and in a very short time, by his skill and his unselfish devotion to his patients, acquired a large practice; and at the time his health began to fail, his was one of the most extensive practices in Harlem. He was a member of the New York Academy of Medicine, the Society of Medical Jurisprudence and State Medicine, and the Harlem Medical Association. About three years ago he became afflicted with diabetes, and denying himself the proper rest and recreation, he gradually broke down an iron constitution. The immediate cause of his death was an attack of remittent fever. He leaves a widow and five children.

Pine-apple Juice is said to be largely employed by the negroes of Louisiana in cases of diphtheria. The success of this popular treatment is said to be eminently satisfactory.

The National Women's Health Association of America was organized in Philadelphia, July 23d, with Caroline Dodson, M.D., as President. Its object is to bring the laity and the medical profession into closer relations by the discussion of health topics.

Death Due to Vesical Endoscopy.—Dr. Albarran reports the death of a patient who had submitted to vesical endoscopy. The urine, examined after death, contained pyogenic bacteria.

The Cholera still Spreading.—Southern Europe is growing extremely nervous over the recent sudden spreading of the cholera, both in Spain and in the Red Sea districts. The prevalence of the epidemic in the latter section, although geographically remote, is far more menacing than its progress in Spain. At this season of the year swarms of pilgrims are concentrated upon Jeddah and Mecca, both of which places are veritable pest houses. Yet Moslem fanaticism and fatalism render quarantine impossible. Caravans resolutely throng the infected centres, and popular superstition prevents their return being impeded. The result must necessarily be that very soon Egypt, Tunis, and Algiers, and, in fact, the whole Mediterranean coast, will be overrun with the plague. It may be impossible to hold immunity for Naples and Marseilles. Both the French and Italian governments seem keenly alive to the danger, and are doing all they can to avert the devastation, but the best science can do is really very little. We practically know no more about either warding off the cholera or fighting it at close range than in the beginning of the memorable scourge of 1884.—*The New York Times.*

Do Medical Women Make a Living?—The *New England Medical Monthly* says, editorially, that there are not twenty medical women in New England to-day who are making a living by the practice of medicine. This may be true; but there are more than that number in Philadelphia who are making a fair living by the useful and honorable practice of medicine.—*Times and Register.*

Medical Reforms in Russia.—Russia is endeavoring to stamp out syphilis. In each district a special doctor is appointed to look after this disease exclusively, treat it, and enforce sanitary precautions. Special travelling dispensaries are provided to bring medical aid to the sufferers, and pecuniary aid is given to the families of syphilitics who are confined to the hospitals. The Russian government has also recently enacted some very stringent laws against the adulteration of food and drink. Any person guilty of adulterating any article of food will be liable to a fine of $200, or imprisonment for three months, for the first offence, double this penalty for the second, and deprivation of all rights as a citizen for the third.

Death of Dr. W. N. Blakeman.— Dr William Nelson Blakeman died August 10th, at his home, 28 West Thirty-seventh Street, in the eighty-sixth year of his age. He was one of the founders of the New York Institution for the Blind, the New York Infant Asylum, and the Society for the Relief of Widows and Orphans of Medical Men. He was a member of the American Medical Association, the New York Academy of Medicine, State Medical Society, County Medical Society, and of the New England Society.

Antipyrine Dangerous in Typhoid Fever.—Dr. Jeffery of Richmond, Va., has found that in typhoid fever antipyrine reduced the temperature for the first few days, but afterward had no effect. He thought the drug too depressing to be safe, and that it did great harm in suddenly reducing high temperature, thus obscuring the true nature of the disease.

Treatment for Agalactia.—Dr. Messinger has used the following treatment successfully in cases of agalactia: Daily massage of the mammary glands; aloes in divided doses; cold sponging and friction of the mammæ morning and evening. After the third application of the massage, he noticed a bluish net-work of vessels on the anterior surface of the thorax. After the sixth, milk could be pressed out from the nipples, and after the sixteenth the flow of milk was usually fully established. The massage was applied by carefully stroking the gland, from the nipple centrifugally in all directions, with a fine foam of soap, in order to evacuate the veins, the masseur standing at the head of the patient.

British Comment on the Execution by Electricity.—Says a London correspondent in the *New York Times*: "English newspapers invested unprecedented sums of money in cable accounts of Kemmler's execution, and the Americans themselves can scarcely have taken greater interest in the ghastly episode than was exhibited everywhere here. Ordinarily, a certain section of the British press treats American affairs with judgment and candor, but in this instance there is no exception to the rule of stupidity in their comments. On all sides the humanitarian impulse which dictated the change is entirely ignored, and the experiment is wildly denounced as a wanton and flippant lapse into barbarism. Such editors as habitually abuse America leaped to the use of the incident as illustrating our native brutality, while the intelligent remainder for once lacked the sense to see what the thing really meant. Opponents of capital punishment throughout Europe seem convinced that the harrowing story sent out from Auburn will create a powerful and wide-spread sentiment against the death penalty in any form." We may add that this wide-spread sentiment will do credit to every nation claiming to be thoroughly civilized, and that we hope to see the day when the State will no longer take life, but use every possible precaution against its being taken.

The Health Department of Providence, R. I., has issued a circular which contains the following suggestions for the prevention of phthisis: 1. No person with consumption should ever spit on the floor or in the street. If handkerchiefs or bits of cloth are employed, they should be at once disinfected or burned. A good plan is to use a small, wide-mouthed bottle with a rubber stopper. The contents should be thrown into the fire and the bottle and stopper thoroughly scalded with boiling-hot water every day. 2. The dishes used by a consumptive should be at once scalded, and the unwashed underwear and bed-clothing should not be thrown with that of other persons, but should be thoroughly boiled as soon as possible. 3. When a person with consumption has diarrhœa, the discharges from the bowels should at once be disinfected, as at this time they contain the disease germs. A good way is to add a half-teacupful of fresh chloride of lime, or fill up the chamber vessel with boiling water. 4. No one with consumption should sleep in the same room with another person, and the room occupied by a consumptive should be thoroughly cleansed as often as possible. 5. No mother with consumption should nurse an infant, and children ought never to be taken care of by a consumptive person.

The Ernest Godard Prize of $100 will be awarded at the close of this year by the Society of Biology of Paris. Competing essays are to be sent to the secretary, 15 Rue de l'Ecole de Médecine, Paris.

Consumption of Opium.—The total annual home consumption of opium in China has lately been reckoned to be about forty-one million eight hundred thousand pounds.

Hydronaphthol is recommended by Dr. Clarke in typhoid fever, green diarrhœa of infants, dysentery, and ordinary diarrhœa. He gives two to three grains every two hours. In flatulent dyspepsia and dilatation of the stomach it is of little use. Nausea is caused in some cases.

The Chicago Medical Society Denounced.—The Omaha Medical Club is setting an excellent example to the men running the Chicago Medical Society, by its war on quacks. The enforcement of the medical practice act in Chicago is left to the overburdened State Board of Health, while the Chicago Medical Society wars on its own members who are desirous of elevating the status of the profession by disciplining members guilty of alliance with blackmailing newspapers in their attack on reputable medical men. The Omaha Medical Club, however, does not have the cheap medical politicians for its leaders, such as now constitute the ruling minority of the Chicago Medical Society. The Chicago medical profession should realize that only by its own efforts can the city be rid of the charlatans who subsidize the local newspapers. The Omaha and New York profession have set it examples meriting emulation.—*Medical Standard.*

Sir Spencer Wells is the Bradshaw lecturer at the Royal College of Surgeons for the year 1890. The lecture will be given in November.

Uterine Procidentia in an Infant.—A Norwegian physician reports the case of a seven-days-old infant which was attacked by diarrhœa resulting in severe straining, followed by rectal and vaginal prolapse. The next day there was uterine procidentia. The uterus was replaced but prolapsed, and so continued until the child's death, six weeks after.

An Italian Crusade against Quackery.—The Italian Minister of the Interior has sent a circular to all the prefects in the kingdom, pointing out that in many parts of Italy dentists do not confine themselves to the practice of their own art, but sell medicines, plasters, and ointments, which they declare to be good for all kinds of disease, and in other ways infringe on the prerogative of duly qualified medical men. He calls on the prefects to use every legal means of suppressing "not only the wrongful exercise of the healing professions generally, but more especially the pompous display of such illegal practice in public places." The mayors of communes are directed to absolutely forbid such practitioners from occupying public spaces.

As it was Formerly.—A statute of Henry VII. runs as follows: The practice of the healing art should be limited to those persons that be profound, sad, and discreet, groundly learned, and deeply studied in physic.

A French Student of Medicine on German Students.—In the *Lyon Médical* a French student of medicine has published his impressions of German students and student-life. He says that, at first sight, it would appear that German students devote less time to study, and more to pleasure and extraneous pastimes, than the students of France. But closer observation reveals the fact that in German universities, just as elsewhere, there are students who study very much as well as those who study very little. The less studious ones attract public notice to a much greater extent than their diligent companions, and hence the error of supposing all of them to be uniformly lazy. Excessive beer-drinking and duelling are indulged in by an insignificant minority. The bulk of the inscribed students rarely miss a clinic or a lecture, although attendance is not at all compulsory.

Everybody is a Job when the boils are on the other fellow.

Society Reports.

International Medical Congress.

TENTH SESSION.

Held at Berlin, Germany, August 4, 5, 6, 7, 8, and 9, 1890.

(Special Cable Report to the MEDICAL RECORD.)

(Continued from p. 160.)

No General Meetings on Thursday and Friday.—No general meetings were held on Thursday and Friday, the entire days being devoted to section work.

Large Number of Papers Read before Sections.—A great number of papers have been read in the various sections, some few being of considerable interest. The section meetings were, for the most part, held in the Exhibition building, where ventilation was defective and much suffering was caused by the heat. The halls opened one into another, and much confusion was created by the passing of persons to and fro through the building, the noise sometimes being so great that it was impossible to hear the speaker when sitting at a little distance.

German Papers only Listened to.—Unfavorable comment was made by some that papers in the German language only were listened to with attention. During the reading in French or English, the German members left the meeting or walked about and conversed, thus causing great annoyance to the speaker and those who desired to listen. In one section the member appointed to read a paper in English refused, saying it would not be listened to, and he did not wish to waste his time. The paper was therefore read by title.

Balls.—On Thursday evening balls were given in honor of the Congress. On account of the large number of guests it was found impossible to entertain all in one place, so five different balls were given, in the Central Hotel, Kaiserhof, Imperial Hotel, the Philharmonic, and the Zoölogical Garden, all being well attended, that at the Philharmonic being the largest.

Court Reception and Excursions.—Friday afternoon there was a court reception given to about five hundred selected guests, and several sections made excursions to Potsdam and the lakes of Havel. Friday evening, as also every evening during the week, various private dinners and receptions were given by Berlin physicians to specially invited guests. Many sections were also entertained by resident chairmen or special medical societies of Berlin.

Visit of the Empress Frederick.—The Empress Frederick visited the Exhibition Saturday morning, accompanied by a maid of honor, and was escorted through by the Committee.

Final General Session.—On Saturday morning the last general session was held in the Circus Renz. The first address was that of PROFESSOR WOOD, of Philadelphia, which had been postponed from Wednesday.

Anæsthesia.—Professor Wood took for his subject "Anæsthesia," which shared with antisepsis, he said, the honor of being one of the two epoch-making discoveries of modern times. Although both had been instrumental in saving multitudes of human lives, yet both had also been the means of destroying life. Antiseptic agents, as now employed, have nearly ceased to be dangerous, but anæsthesia is even yet almost daily adding to the number of its victims, and the problem of how to prevent this sacrifice is well worthy the study of this medical gathering.

Nitrous Oxide Anæsthesia is asphyxia, but differs from mechanical asphyxia in the fact that the phenomena present are the result of a lack of oxygen, without any excess of carbonic acid, in the blood. In death from this agent respiration ceases while the heart is still in full activity, and in the few experiments made by the speaker, artificial respiration was always successful in restoring vitality, even after complete paralysis of the respiratory function. Nitrous oxide is the safest of anæsthetics, but is not practicable during long-continued operations. Inhalation is usually followed by sudden rise of arterial pressure, hence there is danger of apoplexy in case of atheromatous arteries.

Comparative Safety of Ether and Chloroform.—The speaker then took up the subject of the comparative safety of ether and chloroform. It was impossible to gather accurate statistics, but the latest figures collected by Lawrence Turnbull showed that the ratio of deaths from chloroform was four or five times that of deaths from ether. The results of the author's experiments to determine the mode of death under chloroform were not in accord with the report of the Hyderabad Commission, for he had proved beyond doubt that chloroform is a cardiac paralyzant, and often does kill dogs by direct action upon the heart or contained ganglia. The difference in results might be explained on the hypothesis that heat, or other climatic conditions surrounding the pariah dog, render the heart less sensitive to the action of the drug than is the heart of the dog bred in northern lands. Supporting this supposition is the fact that chloroform can be given in the Southern United States with far greater safety than in the Northern States of the Union.

The speaker said the following facts in regard to anæsthesia must be regarded as established: First, the use of any anæsthetic is attended with appreciable risk, and no care will prevent occasional loss of life; second, chloroform acts much more promptly and powerfully than ether, both upon the respiratory centre and upon the heart; third, the action of chloroform is more permanent than that of ether; fourth, chloroform is capable of arresting primarily either respiration or cardiac action, but usually abolishes both functions at about the same time; fifth, ether usually acts more powerfully upon the respiration than upon the circulation, but occasionally is a cardiac paralyzant, and may cause death by cardiac arrest while yet respirations are fully maintained.

Treatment.—As regards treatment, the author's experiments proved that amyl nitrite, caffeine, and atropine were of little use, while injections of alcohol or ether increased the danger. Ammonia is of some service, but of all remedies tried digitalis acted most powerfully in stimulating failing circulation. Strychnine also acted efficiently. Alternately elevating and depressing the feet of an animal dying under anæsthesia was sometimes of great service. Most efficacious of all measures was forced artificial respiration by a modification of Fell's method. In concluding, the speaker formulated measures to be employed in case of threatened death during anæsthesia: Give tincture of digitalis hypodermically; draw out the tongue and see that respiration is not mechanically impeded; invert the patient briefly and temporarily; use forced respira-

tion promptly; apply external warmth and stimulation of the surface, and, above all, avoid the exhibition of alcohol.

Dr. Wood's address was listened to attentively, and was very well received. It reflected honor upon American medicine, and Dr. Jacobi is to be congratulated upon having made so happy a selection when he was called upon to appoint an orator from our country.

Antipyresis.—After this came the address of PROFESSOR CANTANI, of Naples, entitled "Antipyresis." The speaker first sought to define fever, during which process there is more rapid consumption of tissues. Not all tissues are consumed at the same rate. In malaria the blood-corpuscles suffer most, whence arises anæmia. In typhoid the nervous tissues are attacked, whence come debility, somnolence, etc. In tuberculosis all parts except the nervous system are implicated; this explains the preservation of mental activity and hopefulness to the very last.

In combating fever we can increase heat radiation or diminish production. The former is of only temporary use. We must employ remedies attacking the fever process itself. Internal antipyretics, however, reduce the temperature only and do not influence the disease itself.

Fever is only an accompaniment of the disease, and the expression of the struggle of the organism with disease-producing agents, and is often an aid to the organism in this combat, and is therefore to be reduced only when itself threatens life.

Professor Cantani regarded cold water externally and internally as the best antipyretic in most cases.

Synchronous Action of Different Parts of the Brain, was the title of the third address, by PROFESSOR MEYNERT, of Vienna. The speaker opposed the theory of specific action of sensory nerves, and believed their excitability to special stimuli was the result of education. Ability to distinguish colors, sounds, and the like is no more congenital than is a knowledge of the alphabet. This theory would remove the scientific prop from some of the exaggerations of the doctrine of descent, for functions begin only with completion of organic form, and the germ holds within itself no functions. The ego is the result of all conscious perceptions collected in cortical substance.

Resisting Powers of Europeans in the Tropics was the subject of the last address, delivered by PROFESSOR STOKVIS, of Amsterdam. Racial pathology is a new science, the object of which is to determine the effect upon individuals of climatic change, and to learn how these climatic influences can be resisted. Study of disease among troops in tropical countries shows many peculiar facts. Native soldiers suffer from tuberculosis more than Europeans, but the latter suffer more frequently from hepatic disease. This, however, is due more to improper diet, especially abuse of alcohol, than to influence of climate. Of late years hygiene has made great advances in the tropics, and the result has proved that Northerners may reside permanently in hot countries without danger, provided they observe hygienic rules. Jamaica was once considered the graveyard of Europeans, but now mortality there is less than in Spain or Italy. The study of racial pathology has already shown that the susceptibility of Europeans, compared with natives, to disease in the tropics is not due to racial peculiarity, but to difference in the mode of living. The speaker urged the medical profession to greater devotion to the new science of racial pathology, the study of which has already led to beneficial results, and promised even better in the future.

The address was exceedingly interesting and well delivered, and caused much favorable comment.

Farewell Address.—PROFESSOR VIRCHOW then delivered the farewell address, and said he hoped the members would carry home the conviction that Germany was great in peaceful pursuits. In science there was no division of races or religions. The speaker thanked the members, and the city, state, and imperial authorities for their respective parts in the advancement of the interests of the Congress, and hoped to greet his fellow-members three years hence in Rome.

Closing Speeches.—DR. BILLINGS then spoke in behalf of American members, expressing their thanks for all the courtesies they had received.

PROFESSOR SCHNITZLER, as representative of Austria, also returned thanks to all who had contributed to the success of the Congress. The brilliant meetings in London and Copenhagen had been surpassed by that in Berlin, for there is in the German capital a scientific atmosphere the like of which was never felt elsewhere. He referred especially to the medico-scientific exhibition, which was really one of the most noteworthy features of the Congress, and hoped it would result in the establishment of a permanent medico-technical museum. The work of the Congress was not evanescent, for its influence would be felt always.

Then followed speeches in a similar vein by the medical representatives of Hungary, Japan, and Russia.

In the name of Belgium, PROFESSOR THIRY bore witness to the pleasant impressions which the members of the Congress would carry to their homes from Berlin.

The Swedish delegate, PROFESSOR HOLMGRON, also spoke, dwelling especially upon the close relations between Germany and the Scandinavian nations.

PROFESSOR BOUCHARD then rose to speak in behalf of France, and was received with great applause. He returned thanks in graceful words for the gracious welcome extended to himself and countrymen, and hoped that after the meeting in Rome the Congress would convene in Paris.

Still other addresses by representatives of various nations followed, and finally PROFESSOR BACCELLI, of Rome, expressed in Latin his admiration for German science, his thanks to the management of the Congress, and his high personal regard for Virchow. The latter responded, also in Latin, to the graceful compliment, and then declared the labors of the Tenth International Congress ended.

A Very Successful Meeting.—The Congress must be pronounced on the whole a very successful meeting, both as to the number of participants and the amount of work done. The weather was very warm, but was favorable in that there was no rain. Critics disposed to grumble could of course find good cause for so doing, but any shortcomings of management were excusable because of the unexpectedly large attendance.

The total number of members was 5,737, of which 683 were from the United States and Canada, 3,180 from Germany and Austria, and 179 from France.

The social part of the Congress closed with a reception in Kroll's Garden, given by the Berlin physicians and their wives to the members. It was an elegant affair and largely attended.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 5, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Bacteriological Researches in Yellow Fever.—GEORGE M. STERNBERG, Surgeon, U. S. A., spoke upon this subject: In 1879, as a member of the Yellow Fever Commission sent to Havana by the National Board of Health, he devoted himself especially to a search for the specific infectious agent in the blood of patients in various stages of yellow fever. The result of this research was negative.

Extended researches made during the past two years, by the most approved bacteriological methods, fully confirm this negative result. Exceptionally, micro-organisms are found in cultures from the blood and tissues, even when the autopsy is made very soon after death, but the bacillus encountered most frequently has been identified as the *Bacterium coli commune* of Escherich, which is constantly present in the intestine of healthy persons, and consequently cannot be the specific pathogenic agent in yellow fever. Other micro-organisms associated with this are found so exceptionally and in such small numbers that no special significance can be attached to their presence.

The examination of thin sections of the liver, kidney, and other organs, stained by the most approved methods for demonstrating micro-organisms, gives results corresponding with those obtained by culture methods.

That various micro-organisms are present in small numbers in the liver and kidney (and presumably in other organs) at the time of death, is shown by preserving fragments of considerable size in an antiseptic wrapping, which destroys all micro-organisms which may have accidentally fallen upon the surface of the fragment and prevents the entrance of germs from without.

Such a fragment, preserved for forty-eight hours at a temperature of 27° C. (80.6° F.), always contains a large number of bacilli of different species, which have evidently developed from scattered bacilli present in the organ from which it was taken at the autopsy.

These bacilli are for the most part anærobics, or facultative anærobics, and do not give rise to a putrefactive odor. The tissue containing them has a very acid reaction. Putrefactive organisms are also present, and pieces of tissue kept for a longer time give evidence of putrefactive decomposition.

The micro-organisms present in fragments of liver and kidney preserved in the way indicated have been carefully studied, and numerous comparative researches have been made, since his return from Havana, which show that those most constantly and abundantly present are not peculiar to yellow fever. In cases of accidental death, and of death from other diseases, fragments of liver preserved in the same way have contained the same micro-organisms.

His bacillus N, a large anærobic bacillus, which for a time he thought might be the specific germ he had been in search of, he had found in these comparative researches, and was obliged to exclude it from further consideration from an etiological point of view.

One bacillus, however, which was found in a considerable number of cases of yellow fever, in pieces of liver preserved in an antiseptic wrapping, although not in very great numbers, had not been found in his comparative autopsies. This was a non liquefying bacillus which resembled the colon bacillus in its growth in flesh-peptone-gelatine and in its morphology, although it was somewhat larger. It was also more pathogenic, especially for rabbits. This was his bacillus X. Not having excluded it by his comparative researches, he looked upon it as being possibly the specific yellow-fever germ, but had not been able as yet to obtain any satisfactory experimental evidence that such was the case.

This same bacillus was found in the contents of the intestine, where it was associated with a variety of other bacilli, some of which were strict anærobics and some facultative anærobics. The most constant and abundant of these was the *Bacterium coli commune* of Escherich.

Comparatively few liquefying bacilli are found in the contents of the intestine or stomach, or in cultures from pieces of liver and kidney preserved for forty-eight hours in an antiseptic wrapping. The bacillus of Dr. Paul Gibier has been found in the contents of the intestine in a limited number of cases, but it had been absent in a majority of the cases in which the speaker had made autopsies—forty-three in all—and when present had not been abundant as compared with the non-liquefying bacilli. Nor was it found in any considerable number of cases in his cultures from fæces collected during the lifetime of the patient.

There was, therefore, no good reason for supposing that this bacillus had anything to do with the etiology of yellow fever. And, as a result of his extended culture experiments, he felt justified in asserting that yellow fever is not due to a liquefying ærobic micro-organism.

The micrococcus which Dr. Domingos Freire presented to him as his yellow-fever germ, at the time of his visit to Brazil, grows readily in flesh-peptone-gelatine, and causes liquefaction of this medium. Its presence would therefore be readily ascertained by the culture methods which the speaker had employed. It had not been present in a single instance in his cultures from the blood and tissues or from the contents of the intestine. It was therefore excluded from consideration as being concerned in the etiology of yellow fever.

The Tetragonus Febris Flavæ of Dr. Carlos Finlay, of Havana, is a common atmospheric organism in that city, which Dr. Sternberg had obtained in cultures from the surface of the body of patients suffering from various diseases, and of healthy persons. He had not obtained it in his cultures from the blood and tissues, and considered it definitely excluded as the possible etiological agent in the disease under consideration.

The morphological characters and mode of growth, in various culture media, of the different micro-organisms referred to, and of others encountered in his bacteriological researches, were demonstrated by projecting upon a screen his photo-micrographs and photographs of colonies and test-tube cultures.

A detailed report, containing a full account of the researches made during the past two years in Havana, Cuba, and at Decatur, Ala. (1888), was nearly completed, and would be submitted to the President within a short time.

A Change of Home.—The PRESIDENT stated that this would be the last meeting to be held at this hall, where the Academy had made its home for nearly twenty years. The next meeting will take place at West Forty-third Street, October 2d. The Academy voted affirmatively on the resolution to issue bonds to the amount of thirty-thousand dollars.

At the conclusion of the exercises a collation was served.

SECTION IN SURGERY.

Stated Meeting, January 13, 1890.

ROBERT ABBE, M.D., CHAIRMAN.

Election of Officers.—Dr. Robert Abbe was re-elected Chairman, and Dr. Charles A. Powers, Secretary.

Excised Elbow.—DR. W. T. BULL presented a young man to illustrate the result of excision of the elbow for anchylos, is whichhad taken place in the most undesirable position (a straight line). It had followed T shaped fracture of the lower end of the humerus in December, 1888. Only ten weeks had elapsed since excision was performed, yet the man could flex the arm to an acute angle, and extend it to not quite a straight line. Passive

pronation and supination were possible, and these movements were expected to become voluntary with increased muscular power. The head of the radius and both condyles of the humerus were removed, amounting to about an inch in extent.

Shawl-pin Recovered from a Child's Bronchus.—Dr. Bull also presented a shawl-pin, two inches and a fourth long, the head a fourth of an inch in diameter, removed by tracheotomy from the right bronchus of a child two years of age. The pin had remained in the bronchus five days, and given rise to some pain, loss of appetite, vomiting, purulent expectoration, and some evening rise of temperature. There was marked diminution of the respiratory murmur over the whole of the right lung. The incision was made in the median line, its lower edge on a level with the sternal notch, and he was pleasantly disappointed in being able to withdraw the pin without any difficulty or injury of the trachea.

Free Excision Necessary.—Dr. R. F. Weir remarked that an inch and a half was the least amount which one should excise in order to obtain motion in an anchylosed elbow-joint.

Bifurcation of the Trachea within Easy Reach.—Dr. Weir also remarked that it appeared few surgeons appreciated how readily accessible to instrument, or to the finger, even after a tracheotomy had been made, was the bifurcation of the trachea, at which point foreign bodies entering the air-passages were likely to lodge and demand removal.

Fracture of the Skull.—Dr. Thomas Manley presented a man who had sustained fracture of the skull twice, the first time several years ago, above the occipital protuberance, from which he recovered without an operation after lying in Bellevue Hospital unconscious for several days. The second fracture took place on November 20th last, in the left parietal bone, near the median line, a little back of the coronal suture. A convulsion and some symptoms of hemiplegia appearing toward evening, he chiselled out about the fracture, and when the middle piece of bone was lifted venous blood escaped, indicating, he thought, injury of the longitudinal sinus. Hemorrhage was controlled by a compress. The patient was then about, but there was still a depression, and the bone at the posterior edge of the wound was believed to be slightly necrosed and would require removal. It did not seem that implantation of the removed pieces of bone would have been successful in this case.

Resection of the Intestine for Strangulated Hernia.—Dr. Manley also presented a portion of the intestine which his house surgeon had excised from near the ileo-cæcal valve in a case of strangulated hernia. The patient did very well for three days after the operation, when pain and prostration set in, and death took place during the night. The autopsy showed that two of the sutures had given way.

Fracture through Coracoid Process of the Scapula.—Dr. F. J. L. Hupp presented a man, seventy-one years of age, who fell on the sidewalk, November 20th, striking the shoulder, and was found, when he entered the Presbyterian Hospital, two weeks later, to have fracture of the coracoid process of the scapula, a diagnosis which Dr. Powers confirmed after two weeks of hospital treatment, from the presence of thickening of the coracoid process. He stated that fracture here was very rare.

Angio-sarcoma at the Shoulder-joint; Fracture, Amputation.—The specimen was presented for Dr. Weir by Dr. C. A. Powers, who first saw the patient in Chambers Street Hospital, from whence he was sent to the New York Hospital, where Dr. Weir operated. A man, aged twenty-two, had, ten weeks before, fallen and struck forcibly upon the left shoulder. Previous to that time there had been no indications of shoulder trouble. Immediately afterward he sought medical advice, and was treated for contusion without confinement of the arm. During two weeks there was constant motion of the shoulder-joint, when he fell under Dr. Powers's care, who made a diagnosis of surgical fracture of the neck of the humerus. There was then considerable swelling of the shoulder-joint, which even became greater after he applied a plaster-of-Paris dressing. The hypodermic needle only withdrew blood. Four or five weeks after the injury the patient was sent to the hospital, and Dr. Weir made an incision down on the outer surface of the shoulder and found a cavity of considerable size filled with fresh and clotted blood; also fracture through the surgical neck, with disorganization above and below. The pathologist found no signs of malignant change in the particles removed, but as the swelling continued Dr. Weir felt that it was a neoplasm, and amputated at the shoulder-joint. The patient was very weak and succumbed to the operation. The pathologist then found typical angio-sarcoma.

Thought the Fracture caused the Angio-sarcoma.—Dr. Powers thought the fall produced the fracture, and motion in the arm two weeks afterward hastened, or possibly caused, the sarcoma.

Thought the Angio-sarcoma led to Fracture.—Dr. Weir said the question came to his mind whether the neoplasm of the bone did not exist first, and make fracture easy at the time of the fall. He had once seen a case of fracture of the thigh which evidently had resulted from sarcoma, although the surgeon who treated the patient had not recognized this cause. In this case, had there been ordinary fracture without sarcoma, the patient could not have gone two weeks with the arm free from pain; besides, if the neoplasm developed after the injury, its growth was remarkably rapid. The case also showed that clinical experience was sometimes worth more in diagnosis than microscopical examination of structures removed.

Dr. A. Jacobi said he had not the slightest doubt but what the sarcoma had developed before fracture took place, for such was the rule, and not the reverse. Slight injury would cause fracture of the diseased bone. For instance, a syphilitic bone would sometimes give way under muscular action while the man lay in bed.

Enormous Polycystic Kidney; Nephrectomy.—Dr. R. F. Weir presented a polycystic tumor, weighing over two pounds, measuring over ten inches in length, five in breadth, and four in depth, removed from a woman, thirty-three years of age. It had been felt through the abdominal walls as an elongated mass containing nodules, which could be distinguished from tumor of the spleen only by inflating the gut when this rose over the tumor. The patient's condition was good, barring pain in the abdomen and down the left thigh, and size of the tumor. Urea was diminished one-half, some albumin; specific gravity a little low, no casts. The tumor was enucleated, the vessels and ureter tied, and the opening in the posterior wall of the peritoneum, three inches in length, closed by sutures after a drainage opening had been made in the loin from under outward. The operation was performed Friday, and the patient was now doing well. Usually in such cases both kidneys were diseased. This lesion, probably here an acquired one, was also found in intra-uterine life, and children born with it seldom became of age.

Polycystic Kidneys in Poisoned Rats.—Dr. Morris said he once had occasion to experiment on some rats, giving arsenic to a large number, which killed immediately only a few, and three or four months later, on killing forty or fifty with strychnine, he found in most of them polycystic kidneys. Had the arsenic previously administered caused the change in the kidneys?

Intra-capsular Fracture of the Hip.—Dr. A. M. Phelps presented a specimen found in the dissecting-room in a subject who had had suppurative disease. There was an old intra-capsular fracture at the hip-joint, new bone having been thrown out around the head. An abscess cavity led through the acetabulum into the pelvis. The case showed that it was impossible to treat all these cases of hip-joint disease successfully by splints, for here nothing but operative procedures would have answered.

Plaster Casts which will not Break.—Dr. Phelps also showed a plaster-of-Paris hand covered by plumbago and a precipitate of copper, which rendered it non-breakable and improved its appearance.

Dr. James E. Kelly then read a paper entitled "Operative Treatment of Hernia, Syphilitic Lymphadenitis, and Hydrocele of the Cord."

Operations for Hernia Diminishing.—The Chairman remarked, in calling for discussion on the paper, that the general drift of surgical feeling at present was to avoid operating in many cases which would have been operated upon three or four years ago.

Different Methods about Equally Successful.—Dr. Weir agreed with the remark just made by the Chairman. Surgeons had for several years past tried to devise a certain method for curing hernia, and they had not yet succeeded. No method was entitled to special consideration which had not been put to the test for at least two years, and so far only Macewen's, in that surgeon's own hand, had given a better result than seventy per cent. of cures, and all had a mortality rate. Every method put forward showed for some months a large percentage of cures, but relapses took place later. In a small or recent hernia he could promise a cure by operative measures, but not in others. He inclined to restrict the operation to this class of patients, and to those having distressing large hernia; in these, if recurrence took place, the resulting hernia was easily controlled.

No Longer Enthusiastic.—Dr. Bull said that some years ago his enthusiasm regarding the treatment of these cases was not less than that of the author's, and it continued until time elapsed to show the results. At the end of two years there was a good proportion of cures; at the end of three there were fewer; at the end of four, five, and even six years, it was hard to find a case in which there had not been recurrence. He agreed with the author that cases should not be operated upon which were comparatively safe with the truss. Indications were, strangulated or irreducible hernia. He did not think the open method of McBurney could be called the simplest, nor was it well to destroy the obliquity of the canal. At the Hospital for the Ruptured and Crippled relapses were seen in cases operated upon by every method, by various surgeons.

Time may yet give us a perfect operation, so thought Dr. Manley.

Excision of Buboes.—Dr. Syms had operated for buboes in the manner described in the paper, with success.

Why he Doesn't Operate.—Dr. De Garmo said he was frequently asked why he did not operate upon hernia oftener than he was accustomed to do. He had to answer that his time was taken up largely with treating mechanically the failures of other operators. This was especially true of so-called open operations. These were the worst to manage mechanically when relapses had occurred. Instead of having a hernia coming out through the external ring, surrounded by fibrous teudons, it met no resistance except at the internal ring, where the parts were known to be soft and yielding, and difficult to control by truss and pad. Contrary to his former custom, he now advised gymnastic exercises while wearing the truss.

Dr. Kelly closed the discussion.

A Rare Case of Urinary Extravasation down the Thigh from Deep Urethral Rupture.—Dr. Eugene Fuller read the history of the case.

Urinary Extravasation Among the Glutei.—Dr. Powers said that of the many cases of urinary extravasation which he had seen at the Chambers Street Hospital, in but one did the urine take an unusual course. In that instance it appeared in the buttock on both sides, causing swelling and bagginess. Free deep incision was made, and the patient made a slow but complete recovery.

Dr. Brewer had, nine years ago, seen a case of pus in the lower part of the pelvis take the same course as the urine in the case related by Dr. Fuller.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 23, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Pachymeningitis Interna Hæmorrhagica.—Dr. William P. Northrup presented a card specimen showing the early stage of pachymeningitis interna hæmorrhagica. The specimen was from a child, two months of age, the subject of congenital syphilis.

Pachymeningitis Hæmorrhagica.—Dr. E. D. Fisher presented a specimen showing this lesion. The patient had presented no especial symptoms during life, except a mental dulness, and no diagnosis had been made. At the autopsy there was found to be an old pachymeningitis with recent hemorrhage.

Aneurism of the Aorta.—The patient from whom this specimen was removed was a man, fifty-five years of age, born in Switzerland, who was also a sufferer from goitre. He had been in bed all the time, and presented no symptoms whatever pointing to aneurism. At the autopsy there was found an aneurism involving the ascending aorta and the arch. The heart was also somewhat dilated. The question that had occurred to the speaker was whether there were any connection between the aneurism and the goitre. There had been no dyspnœa noticed, for the man was always in bed, and there had, in fact, been no symptoms at all except marked stupidity.

Diaphragmatic Hernia.—A third specimen was one removed from the body of a woman at autopsy. The woman had had a strangulated inguinal hernia, and had vomited a great deal, and was much exhausted. The strangulation was relieved, but she died suddenly soon after. At the autopsy there was found a small opening in the diaphragm through which about half of the stomach had passed.

Extensive Destruction of Brain Tissue.—The fourth specimen was one removed from an old case of hemiplegia. The dura was found adherent to the convex surface, especially along the longitudinal fissure. There was atrophy and sinking in of the convolutions, and on cutting into them the left lobe was found almost completely disorganized. The speaker thought that this was due to the hemorrhage, the only question being whether there had been also an abscess of the brain.

Chronic Endocarditis with Vegetations.—Dr. H. P. Loomis presented specimens showing chronic endocarditis with vegetations and secondary sepsis, simulating acute ulcerative endocarditis. The patient, John M——, was brought into Bellevue Hospital in a semi-conscious state, and nothing concerning his previous history could be learned. When seen by the house physician the patient was sitting up in bed suffering from intense dyspnœa. There was general dropsy and cyanosis was marked. It was impossible to diagnose the cardiac lesion by the murmurs. The temperature was 104° F.; the pulse was 140, feeble and irregular. Petechial spots were visible over the entire body, more especially on the lower extremities. Ten hours after admission the patient died.

Autopsy.—The pericardium was normal. The heart was hypertrophied and weighed sixteen ounces. There was dilatation of the left ventricle, the thickness of its wall being only 8 mm. All the aortic cusps were thickly coated with vegetations of a grayish yellow color, presenting a fungous appearance, and extending from the attached border of the valves for a distance of 2 ctm. The edges of the erosions were uneven, granular, and somewhat hidden beneath the fungating growths surrounding them. The vegetations were firmly attached to the surface of the endocardium, and on microscopical examination were found to be made up of fibrin and granular débris with some cellular elements. At the base of the vegetations was thickened and inflamed endocardial tissue, in which, on staining with fuchsin, were found micrococci. There was stenosis of the mitral valve, but no vegetations or ulcerations were found around the valvular

orifice. Both lungs were normal, with the exception of a gangrenous cavity in the upper portion of the lower lobe of the right lung, close to the root of the lung, 6 ctm. in length and 3 ctm. in width. The edges of the abscess were irregular, but limited by newly formed connective tissue plainly visible to the naked eye, and its cavity contained broken-down pulmonary tissue and cheesy pus. A large vessel leading to the abscess cavity was obstructed by a white thrombus 2 ctm. in length. All the bronchial glands at the root of the lung were greatly enlarged, three of them reaching an enormous size, one being 5½ ctm. in length and 3 ctm. in thickness. Without question the abscess cavity was a gangrenous infarction, and its close proximity to the bronchial glands at the root of the lung led to their septic condition. The spleen was about two and a half times its normal size and contained two large white infarctions 4 ctm. in diameter, together with fifteen or twenty small ones scarcely visible to the naked eye. The kidneys presented the lesions of a moderate amount of chronic diffuse nephritis. Numerous small infarctions were scattered throughout the cortex of both kidneys. The liver was normal. The mucous membrane of the intestines was very anæmic, but presented no pathological lesions. The brain was not examined.

Remarks.—A cursory examination of this case, Dr. Loomis said, would lead one to pronounce it acute ulcerative endocarditis. The high temperature, the petechial spots, the almost typical appearance of the aortic valves, the presence of micrococci, and the multiple infarctions in the various organs, all seemed to bear out this diagnosis. Upon careful analysis, however, the pathological changes were found to be more satisfactorily explained by considering that the micrococci found in the diseased valves were the result of a secondary infection, and not the primary cause of the condition. The speaker presented this case because he thought it represented a type of a large number of cases which are called by many acute ulcerative endocarditis, the chief cause of such a diagnosis being that micrococci are found in the vegetations on the valves. The specimens here presented were from the body of a man who had an old lesion of the aortic valves, as proven by the cardiac hypertrophy and dilatation. Dr. Loomis offered an explanation of the other lesions as follows: From some unknown cause, possibly from a lowered condition of the system, the quality of the blood became changed and fibrinous masses were deposited on the thickened and eroded aortic valves. These afterward broke off and passed to different organs (for white infarctions were found in the spleen and kidneys). In time one of these masses reached the lungs and plugged so large a vessel that necrosis of the pulmonary tissue took place. An abscess formed, and communicated most probably with a bronchus. Bacteria were present, together with the staphylococcus pyogenes aureus. These readily gained entrance to the blood-current, either directly or by the lymphatics, for the enormously enlarged bronchial glands showed that they were infected. The micrococci in the blood found in the already diseased valves a fit soil for their growth, so the vegetations became—not primarily, but secondarily—infected. The speaker had had, during the past year, the opportunity to make a number of autopsies on cases of so-called acute ulcerative endocarditis. Most of these cases, when studied from a pathological stand-point, were similar to the one just presented, and were not true types of acute ulcerative endocarditis, as that term is now understood.

Dr. Ely said that Dr. Loomis's conclusions agreed with those of several investigators in Germany and elsewhere. Dr. Prudden had also found in the course of some laboratory experiments that it was necessary to injure the valves, otherwise the bacteria would not lodge on them.

Interstitial Placentitis.—Dr. Charles N. Dowd presented some microscope slides of a placenta coming away in a case of miscarriage. In the case of a mole which he had presented some time ago there was also interstitial placentitis. The specimens were interesting as suggesting that interstitial placentitis might be more common than was generally supposed, and might perhaps be a somewhat frequent cause of miscarriage. The woman in this instance was perfectly healthy and gave no symptoms of syphilis.

Tubercle Bacilli.—Dr. E. L. Trudeu, of Saranac Lake, presented by invitation some specimens and made the following remarks: "These tubes, marked No. 1 and No. 2, contain pure cultures of the tubercle bacillus on glycerine-agar, and are of interest as illustrating some possible variations in the growth of the microbe. No. 1 was obtained by myself at the laboratory of the College of Physicians, through the courtesy of Dr. Prudden, from the lung of a man who died of acute miliary tuberculosis, and is only the third generation direct from the human lung. No. 2 was brought by Dr. Currier from Europe, and is supposed to have originated from artificial tuberculosis in a guinea-pig, but the data on this point are somewhat uncertain; it has been under artificial cultivation for a long time. The differences in the growths are marked. No. 1 culture consists of dry scales growing very slowly in irregularly heaped and somewhat rounded masses, which can be raised entire on a needle from the subjacent agar without leaving a trace of their presence, these being all the usual characteristics of a pure culture of the tubercle bacillus. No. 2 shows small, white, creamy growths which take place much more rapidly than is the case with No 1, the surface remaining tolerably even until the end of the fourth week of its stay on the thermostat, when it begins to crumple up and present very soon high ridge-like pleats, more especially toward the centre; these cultures are neither dry nor scaly, but are of the consistency of thick cream and adhere pretty closely to the subjacent culture medium. No. 1 grows abundantly on potato; No. 2 but very slightly, if at all. The lesions resulting from the inoculation of both types of growth in animals vary perceptibly, those produced by No. 1 becoming more rapidly generalized, and caseation occurring at an earlier date than when No. 2 is injected. The variations referred to appear to be quite constant, for they are still to be found after the microbes have been passed through a living animal, the plants made from the resulting lesions showing each type to have retained its own peculiarities.

"Up to the present time no variations in the mode of growth of the tubercle bacillus have been recorded. Whether the deviation shown by No. 2 culture and the apparent diminution in its virulence are due to long cultivation and to its attendant artificial conditions of existence is difficult to determine, though similar deviations from the normal have already been noted under similar conditions in several other pathogenic bacteria, and notably in Loffler's diphtheria bacillus. One passage through a living animal does not, however, efface the peculiarities. The morphological appearance of both these microbes under the microscope, the tenacity with which both retain the aniline dyes in the presence of nitric acid, and the approximate similarity of their pathogenic properties (inoculations made with either resulting in nodules identical with those found in tuberculosis) would seem to preclude the possibility of No. 2 being anything but a variation of the tubercle bacillus, especially when we remember that other bacteria (of which anthrax is perhaps the best example) have a wide range of deviation from the normal, not only as to their mode of growth, but as to their morphological appearance and pathogenic properties as well. Indeed it is upon these variations that the principle of successful vaccination in anthrax rests, and this lends an additional interest to the departure from the normal type which these cultures demonstrate."

Culture of the Tubercle Bacillus in a Fluid Medium.—"I also show you here several flasks containing a pure culture of the tubercle bacillus in a liquid medium. As far as I know, the culture of the tubercle bacillus in liquids has never been described, at least not in this country. The growth always takes place at the bottom of the vessel, if the liquid is at rest, in a mucus-like film, much resembling

vesical mucus in urine. After a stay of six weeks in the thermostat this film has become a dense yellowish mass of the same consistency and appearance as bronchial mucus; indeed, you will notice that, curiously enough, these cultures resemble nothing so much as a large lump of phthisical sputum lying on the bottom of the jar. Under the microscope the appearance of the bacilli does not differ materially from that of those grown on solid media."

Lungs in Artificial Tuberculosis.—Dr. Trudeau then showed two sets of lungs taken from rabbits inoculated in the rim of the ear with a pure culture of the tubercle bacillus, and killed two and three and a half months respectively after the inoculation. They both presented the same lesions, but at different stages, the lesions being almost identical with those of acute miliary tuberculosis. They were both literally riddled with tubercular nodules, and large caseating foci were pretty evenly distributed on the pleural surface. These large caseous masses may have been produced at the spots where small lumps of culture have become lodged. The cultures made use of for these inoculations had been grown on potatoes.

Nature's Effort at Repair.—The speaker then presented a third set of lungs, with a drawing which illustrated most strikingly nature's conservative efforts as displayed in artificial tuberculosis. "These organs were removed from a rabbit ten weeks after inoculation of a pure culture of the tubercle bacillus directly into the right pleura and lung. The animal was kept out of doors and under excellent hygienic conditions. No microscopical tubercles are seen in this case to stud the lung and pleura, but several large, fibrous-looking tumors, adherent to the visceral pleura, are visible at the point of injection and at various other places on the surface of the lung and pericardium. These gigantic nodules are seen to consist, on section, of a thick fibrous capsule containing a mass of caseous material swarming with bacilli. The drawing was taken by Dr. Prudden, from the microscopical appearance presented on section of a similar nodule to those attached to the lung under discussion, and shows the encapsulated bacilli in the centre of a very thick fibrous capsule which ends in a narrow pedicle attached to the pleural surface. The bacilli swarm in the centre, diminish in numbers as the capsule is approached, and not a single one is to be seen in the fibrous tissue of which the latter is composed. What would have been the subsequent fate of these microbes thus imprisoned can only be a matter of conjecture, but it does not seem unlikely that either they would ultimately have been obliterated by the steady contraction of the fibrous tissue surrounding them, or that they might have escaped from their mechanical limitations by ulceration, and thus endangered the integrity of the surrounding tissues and the life of the animal. No doubt secondary tuberculosis and relapses in chronic phthisis have frequently a mechanism very similar to that which these nodules illustrate. I have succeeded in obtaining pure cultures of the bacillus, a year after inoculation, from similar nodules taken from the same animal who furnished the specimen for this drawing, and who was apparently in good health and presented otherwise sound organs when killed."

Dr. Prudden asked how early Dr. Trudeau had observed caseatin to occur in artificial tuberculosis.

Dr. Trudeau answered that he had seen it at the end of from the fifth to the eighth week, but if large masses of bacilli were injected, it might appear much earlier at the site of injection, but not in distant lesions.

Chronic Alcoholism in a Boy of Thirteen Years.—Dr. H. M. Biggs presented a specimen of advanced cirrhosis of the liver, taken from the body of a boy, thirteen years of age, in whom were found all the other lesions of chronic alcoholism. When the child was two years old he had an attack of bronchitis, for which the physician prescribed whiskey. He seemed to be fond of it, and his parents allowed him to gratify his taste whenever he desired, giving him money for the purpose. He used to drink about an ounce and a half six or eight times a day. The day of his death he purchased a larger quantity than usual, and drank it all at once. He was found some hours after in a semicomatose condition, from which he never rallied. At the autopsy the liver was found to be markedly cirrhotic, and all the other lesions of chronic alcoholism were present in advanced degree.

Perforation of the Trachea.—A second specimen presented was one removed from a patient who had died in Charity Hospital. He was admitted suffering apparently from anæmia with some bronchitis. He gradually failed and finally developed a dyspnœa which was continuous but marked by paroxysmal exacerbations. There were râles to be heard in both lungs. The patient died in one of these paroxysmal attacks of dyspnœa. At the autopsy gummy tumors were found in the liver, and the bronchial and tracheal glands were very much enlarged. The trachea at its point of bifurcation was compressed, and there was a point of suppuration in one of the cheesy glands which had resulted in perforation of the trachea just at its bifurcation. The dyspnœa was probably due to the bronchitis and compression of the trachea, while the paroxysmal exacerbations were the result of pressure on the laryngeal nerve.

Carcinoma of the Œsophagus.—The third specimen was one of very extensive cancerous disease of the œsophagus, with secondary involvement of the trachea. There were also secondary nodules scattered throughout the body. Seven or eight weeks before the patient's admission to the hospital he had had some difficulty in swallowing which increased rapidly, and for about ten days before death he was unable to swallow any food at all, being nourished by enemata. The liver increased very perceptibly in size during the patient's stay in the hospital. The point of special interest in the case was the rapidity with which the disease must have progressed, since there had been no symptoms of œsophageal trouble until a short time before the patient's admission to the hospital, at which time the carcinoma was already far advanced.

The Society then went into executive session.

Correspondence.

THE TREATMENT OF THE INSANE IN THE GENERAL HOSPITALS.

To the Editor of the Medical Record.

Sir: In your issues of June 28th and July 19th I read with much interest a discussion on the "Treatment of the Insane in General Hospitals," conducted by Drs. W. P. Spratling, of Morris Plains Asylum, and Dr. Frederick Peterson, of New York. I am glad to see a discussion of this kind take place in such a journal as the Medical Record, because it will be read by a very large number of general practitioners who give little or no consideration to the subject of insanity. It is an encouraging sign of the times that very much more discussion of insanity is to be noted in general medical journals now than in times past.

It is unquestionably the duty of every physician in the country to become acquainted with this subject. Any physician is liable to be called upon at any time to treat a case of insanity, and to advise the friends of a patient as to the proper steps necessary to admit the patient to an asylum. Except in the large cities there are no specialists to whom the practitioner can transfer his patient. He must himself examine the patient and make out the certificate of insanity (together with a colleague usually).

Aside from this practical aspect of the question, and that of the immense sums of money annually expended by each State for the support of the insane, there are social questions of momentous importance connected with the subject. It is not the asylum officer or the lunacy board alone that we must look to to inaugurate steps

looking to the prevention of insanity. It can only be done by an awakened and general interest in the profession at large in this great social problem. Is it not a great social outrage, as well as a menace to the mental health of the whole land, that husbands can take their wives, and wives their husbands, home from asylums during a short lucid interval of the patient, and engage in the relation of husband and wife? Yet there are many children born from such a union.

To return to the subject which has engaged the attention of Drs. Spratling and Peterson. The latter says: "It is not precisely clear to me why the character of a general hospital should be changed by the admission of patients suffering from functional disorders of the brain, some of which we call insanity." To me there is just as much reason for separating certain patients suffering from functional (?) disease of the brain as there is for separating certain cases of fever. I think Dr. Peterson would not advocate the admission of cases of typhoid, typhus, variola, and malaria into the same hospital simply because they were all cases of fever. I can readily understand how certain forms of insanity, *e.g.*, melancholia attonita and simplex, stuporous insanity, etc., might be treated in the wards of a general hospital; but how cases with great excitement and violence, such as acute mania, melancholia agitatta, etc., could be placed there I cannot imagine. Dr. Peterson has cited a number of general hospitals where the insane are received and treated, but he has not made clear whether they are treated there continuously until cured, or only a short time and then transferred to an asylum. In the case of Bellevue I infer the latter practice obtains. Salpetrière and Bicêtre, however, retain their patients permanently, much as general asylums for the insane do. But at Salpetrière there is a separate building for the insane; in fact, it is simply an insane asylum which belongs to a hospital plant. In fact it is very similar to the insane department of the Philadelphia Hospital, which is a department of the general hospital, supervised by the same chief resident physician and managed by the same hospital board. This department of the hospital is, like all others, under a regular staff of visiting physicians, just like the surgical, medical, and obstetrical departments; moreover, the material is available for instructing medical students. But the building for the insane department is somewhat apart from the other buildings, and is, in fact, conducted much like other insane asylums.

The Massachusetts General and the Pennsylvania Hospitals each have departments for the insane. In both cases the buildings are removed some distance from the general hospitals to which they belong, and in both cases are distinctly known as insane asylums—the one by the name of McLean's, the other as Kirkbride's.

The fact must not be lost sight of that as a matter of fact the insane were formerly treated in general hospitals, and that for certain reasons they were removed subsequently to hospitals specially built for them. I need only mention Kirkbride's as an outcome of the Pennsylvania Hospital.

So I believe that while it is desirable to treat insane patients in general hospitals, separate buildings will be required if all cases are to be taken in. But if this plan is to be anything more than a name, the department for the insane ought to be in close touch with the remainder of the hospital—not so widely separated as to constitute a distinct plant practically.

Certain forms of acute insanity, however, could be very advantageously treated in the ordinary general hospital, and these hospitals ought to be willing to receive them.

This plan would present one very desirable feature, viz., the patient and his friends would be spared the opprobrium which attaches to residence as a patient in an asylum. It is an incontrovertible fact that a sense of shame and family disgrace is felt by the patient, his friends, and the public generally at the thought of being a patient in an insane asylum. Dr. Spratling's suggestion, that the word "hospital" be substituted for "asylum," will not correct this sense of pseudo-pride. The institution will still be known as the place where "crazy" people are kept.

The chronic cases of insanity, however, are much better off in the ordinary asylum. It must be remembered that the asylums have a number of necessary equipments for the amusement and employment of patients, which are expensive, such as workshops, grounds, farm, etc., affording opportunities for work; chapels, amusement hails, games, etc., affording edification and amusement. This equipment for a general hospital would be too expensive, as these hospitals are usually within city limits where prices for land are high.

THEODORE DILLER, M.D.

ST. LOUIS, July 24, 1890.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 3 to August 6, 1890.

KIMBALL, JAMES P., Major and Surgeon. By direction of the Secretary of War, the ordinary leave of absence granted in S. O. 152, July 1, 1890, from this office, is changed to leave of absence on surgeon's certificate of disability, with permission to leave the Division of the Missouri. Par. 7, S. O. 182, A. G. O., August 6, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 9, 1890.

WALES, P. S., Medical Director. Ordered in charge of the Museum of Hygiene, Washington, D. C

BRIGHT, GEORGE A., Surgeon. Ordered to the Constellation.

MACKIE, B. S., Surgeon. Detached from the Constellation and ordered to the Naval Hospital, Philadelphia, Pa., for medical treatment.

DERR, E. Z., Surgeon. Ordered to the Minnesota.

WAGGENER, J. R., Surgeon. Detached from the Minnesota and ordered to the Kearsarge.

MOORE, A. M., Surgeon. Detached from the Kearsarge and granted three months' sick leave.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 9, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	33	8
Scarlet fever	31	4
Cerebro-spinal meningitis	3	2
Measles	147	10
Diphtheria	42	12
Small-pox	0	0
Varicella	0	0
Pertussis	3	13

The Eiffel Tower to be Utilized.—It is stated that advantage is to be taken of the elevation of the Eiffel Tower to erect a manometric tube to contain mercury, so that at the bottom a pressure would be obtained equal to 400 atmospheres (roughly speaking, about 6,000 pounds, or two and a half tons to the square inch). M. Cailletet proposes to utilize this enormous pressure in his investigations concerning the liquefaction of gases.

A Remarkable Accident.—A man employed in the chlorate of potash department of Messrs. Muspratt's works, at Flint, Wales, was entering the premises when he struck a light against his trousers. The wearing apparel was so impregnated with chlorate dust that it ignited instantaneously, and he was immediately enveloped in a mass of flame. A fellow-workman promptly threw him into a pool of water, but when extricated it was found that he had been so fearfully burnt that no hopes are entertained of saving his life.

Medical Clubs not a Success.—A fatal Nemesis seems to hang over clubs which are promoted for and by the medical profession. Only recently we had an excellent example of this baleful tendency in London. Parsons and lawyers and the military we may say, with all due respect to those honorable callings, eat, drink, and are merry in these places of light, peace, and refreshment. To us, as doctors alone, clubland is that promised portion flowing with milk and honey which we are forbidden to enter and enjoy. The latest venture in this direction is a club entitled "The Aberdeen University Club," the creation of which it is needless to specify. But though situated in Union Street of the Granite City, members of any University are eligible for membership. Indeed, according to the prospectus, everybody and anybody may enjoy the privileges of membership save only persons attending college classes for the purpose of study. This boycott of the students throws a curious side-light upon the relations between teacher and taught in Aberdeen.—*Hospital Gazette.*

The Jacksonian Prize for the year 1889 has been awarded to Mr. Walter George Spencer, London, for his essay on "The Pathology, Diagnosis, and Treatment of Intra-Cranial Abscess and Tumor." The subject for the year 1891 is "The Pathology and Treatment of Diseases of the Knee-Joint."

Child-Wives in India.—In a pamphlet recently published by a native Indian author, Behramji Malabari, he invites Englishwomen to realize, if they can, the meaning of such expressions as "infant marriage," "baby-wife," "girl-mother," "virgin widow." If a "wife" becomes a "widow" even while she is still an infant, a widow she must remain all her days. The most ill-fated of these child wives are, of course, those who become wives not merely in law, but in fact, at ages varying from ten to twelve. "Girls of twelve and thirteen," writes Mr. Malabari, "have to bear the burdens of wifehood and motherhood," and he adds, that "not a few of these married martyrs succumb to the shock of the first child-birth." This hideous practice of child-marriage explains most, if not all, of the poverty and the misery—the physical and moral degradation—to be seen in hundreds of thousands of native Indian families. One of the worst forms of girl-marriage is known as "marrying girls to the gods," which practically means slavery of body and soul to the priests, great numbers of whom live upon the immorality of their girl-wives. This dreadful custom of child-marriage is one which the British Legislature, that had the courage to abolish suttee, has been afraid to meddle with. It was universal. To uproot it would have seemed like uprooting native society. But the custom is doomed, nevertheless. The condemnation of child-marriage is coming from the people themselves. Its disappearance will not be the work of a day. Mr. Malabari's own countrymen, the Parsees of Bombay, have for years been laboring in the good cause with zeal and intelligence. The educated and intelligent natives of Madras are petitioning for fixing the minimum age of girl-marriage at fourteen years.

London's Water-Supply to be Improved.—The *London Times* says that: "It would be a great security for the health of London if it were practicable to abandon the Thames and the Lea as sources of supply. Both rivers contain an enormous amount of sewage, especially in times of flood, when the contents of foul ditches and of filth receptacles of all kinds, as well as the crude sewage from low-lying sewage farms, are washed into the stream. It must be owned that, considering the amount of pollution which the water receives, it is wonderful that the death-rate of London is so low, and especially that the cases of those diseases which are especially associated with bad water, continue to diminish. But it is impossible to avoid some apprehension as to what might happen if there were, for example, a considerable epidemic of cholera or of enteric fever at Staines. Some years ago there was a sudden outbreak of the latter disease throughout the Caterham Valley, and between three and four hundred cases occurred nearly simultaneously. Dr. Thorne, one of the staff of the Local Government Board, investigated the outbreak, and showed quite clearly and conclusively that it was attributable to a well at the water-works being fouled by a single workman who had a very slight attack of typhoid fever. That water, though it would have been pronounced of the highest quality if judged by any tests that analysis could supply, spread disease through an extensive district, and if there were not a single case, but an epidemic, at Staines, where the sewage runs direct into the river, a rather risky experiment would be tried upon pretty nearly three millions of people as to the effect of filtration in removing disease-germs so minute as to be undistinguishable by the microscope. Even if it cannot be definitely proved that the health of London is endangered by the present supply, it is a nasty idea that Londoners are now drinking the sewage of a huge population. The only cure is the establishment of a single water authority which could resort to other sources.

Kraurosis Vulvæ.—This term was first applied by Breisky to general atrophy of the external genitals in the female, especially when the atrophy occurs prematurely. It is now known to be more common than was at first supposed. Pruritus is usually present, and the patient is apt to get anxious through acquiring the belief, always repugnant to the female mind, that she is "not formed like other women." Dr. Ohmann-Dumesnil has written on kraurosis vulvæ in the *Monatsheft. f. prakt. Dermatologie.* He has collected thirty-five cases, recorded by Breisky, Janovsky, Heitzmann, and himself. The hard patches of epidermis were frequently scraped, and the parts were stimulated by caustic or astringent solutions. Tannin, or a one per cent. solution of salicylic acid appeared to be safe and efficacious. Constitutional treatment was always important, especially in nervous subjects, or where neuralgia in the anterior crural or in other nerves was present.

Professional Writing in Lay Papers.—A very regrettable tendency has manifested itself for some years past on the part of medical men, more or less known to the public, to cultivate notoriety—for it can hardly be called fame—by contributing popular articles on medical topics to the lay reviews. It is probably useless to protest against a practice which has for its object less the enlightenment of the public on any particular subject, than the desire to associate one's name with the treatment thereof. It is an insidious form of advertising which escapes censure at the hands of the medical authorities, but cannot raise the writer in the estimation of his fellows or of the intelligent public. Authors, however, probably care little for the latter, preferring the increment of income likely to accrue from the public which cannot rightly be described as intelligent. It is, nevertheless, within the power of medical men as a body to make the "irrepressibles" understand that they are violating the spirit if not the letter of the regulations.—*Hospital Gazette.*

The Maine Medical Association held its annual meeting in Portland, on June 10th, 11th, and 12th. The following officers were elected: *President,* Dr. S. B. Hunter, of Machias; *First Vice-President,* Dr. B. B. Foster, of Portland; *Second Vice-President,* Dr. F. L. Dixon, of

Lewiston; *Corresponding Secretary*, Dr. O. W. Stone, of Camden.

The Delaware State Medical Society began its second century, on June 13th, at its 101st annual meeting in Wilmington. The election of officers resulted in the choice of the following: *President*, Dr. Joshua A. Ellegood, of Laurel, Sussex County; *Vice-President*, Dr. Ezekiel Cooper, of Camden, Kent County; *Secretary*, Dr. W. C. Pierce, of Wilmington: *Treasurer*, Dr. Joseph H. Chandler, of Centreville.

The Pioscope.—The new instrument, called the pioscope, consists of a glass dial about two inches in diameter, with a white centre circle, and six different colors radiating from the circumference of this circle to the circumference of the dial. These colors are marked "less fat," "very fat," "cream," "very good," and "poor." A drop of milk is placed under the white centre, and by some chemical process its color is changed corresponding with one of the five shades, thereby indicating its quality. In some recent experiments with the pioscope, milk, which the lactometer registered eighty per cent., was of the shade of pure, but with ten per cent. of water added it registered very poor, that is, less solids or cream. The highest test went up to a hundred and ten, and the lowest down to sixty-five, according to the lactometer. Dr. Le Tourneux is of the opinion that the best test was by means of the microscope, although the pioscope experiments proved quite satisfactory.

Lunatics in China.—In China acts of homicide or murder committed by lunatics are rare. In that country the iron hand of justice works inexorably, and the plea of insanity is not admitted as a mitigation of punishment. A laborer was recently sentenced to death in the usual manner appointed for the crime of parricide, while the relatives, who had neglected to inform the district authorities that the man was insane, were each sentenced to receive a hundred blows with a stick. According to Western ideas this punishment of lunatics is cruel, but there can be little doubt that the severity adds largely to the protection of the public, as is evidenced by the rarity of crime by lunatics in China. There are few lunatics so mad as to be altogether deficient of self-control, and the knowledge possessed by all Chinese that, whether mad or sane, they will be punished for any crimes they may commit, acts upon all alike as a deterrent. In England they have gone to the other extreme. The slightest evidence showing that a man or woman's mind is unhinged upon certain points is considered sufficient to shield them from the consequences of any crime they may commit, even when that crime is perpetrated with an amount of cunning and forethought sufficient to show, beyond doubt, that the person committing it was perfectly aware of wrong-doing, and was sane enough to adopt every precaution against discovery.

Urobilinuria.—According to Hayem this condition, when habitual, persistent, and varying in degree, has a clear pathological significance, and is a valuable indication in forming an early diagnosis in diseases of the liver. He regards urobilin as the characteristic coloring matter of hepatic incompetency. He has observed urobilinuria in the following cases: 1. At the beginning of alcoholic cirrhosis. 2. In cardiac patients in whom the liver is not enlarged, it may be an indication of incipient hepatic lesions. 3. In numerous acute affections when observed in alcoholic patients, such as typhoid fever. When a large proportion of urobilin is detected in this affection, reserve should be made with regard to the prognosis. 4. In newly delivered and nursing women. 5. In most forms of cachexia. Urobilin has a feeble coloring power, and is found in pale urine. The deep coloring of urine observed in certain affections (fever with perspiration, lassitude, overfatigue) is usually due to urochrome.

Russian Punishment for Adulteration.—Severe measures have recently been taken by the Russian Government against adulteration, and the sale of injurious substances as food. Persons convicted of these offences will be liable to a fine of 300 roubles, or to imprisonment for three months. For a second offence these penalties will be doubled, and a third conviction will entail the loss of civil and political rights. Mr. Bright's doctrine of *caveat emptor* evidently finds no favor in the eyes of the Czar. Our own "free and enlightened" country might with advantage take a hint from such truly benevolent despotism.—*The Lancet.*

The Fields of Vision in Hypnotism.—In a paper which appeared in the *Neurologisches Centralblatt*, Morawosik records the curious case of a hysterical woman, aged twenty-three, whose fields of vision could, during the waking condition, be considerably enlarged by various peripheral stimuli, such as the application of warmth to the skin, or a tuning-fork to the ear; and, during the hypnotic state, a sad suggestion narrowed the field, and a cheerful suggestion considerably enlarged it.

Cystic Degeneration of the Brain.—Pick has made a careful study of eight cases in which multiple cysts were found in the brain. In his account of their character, position, and varieties, and also in his opinion that they are due to dilatation of the perivascular lymph-spaces, he confirms the views of previous authors; and he considers that the obstruction causing the dilatation of the spaces is due to some congenital mischief.

Morbid Desire for Operations.—Professor Leyden, of Berlin, not long since, showed to his class at the Charité Hospital a case belonging to that category of hysterical women who have a morbid desire to have operations of the most painful character performed without any anæsthetics being used. They do not experience pain; on the contrary, that which produces all the accompaniment of pain in others produces in them pleasure. The patient shown by the professor to the class was a young lady, who had, during a hysterical paroxysm, fractured her jaw and injured the facial artery. The injury was a serious one; the facial and the carotid arteries had to be ligatured, and part of the lower jaw removed; but the patient insisted in having the operations performed without any anæsthetic, and afterward informed the operator that she had experienced great pleasure from the operation.—*London Medical Recorder.*

A Novel Operation for Cataract.—"Drs. V—— and M—— lately performed an operation on Mrs. D. S——, removing the left eye, which was made necessary by a chronic cataract and iritis, which had formed on the eye, and would in a short time have caused the other eye to become blind. The operation was entirely successful, and the patient is resting easy, and has every possible chance for a speedy recovery."

The preceding item, taken from a daily paper published in Ohio, may be of interest to eye surgeons generally, as it gives a method of operating for the cure of cataract by which a percentage of one hundred uniform results may be obtained, both as to the amount of sight and the certainty of no return of the cataract, either acute or chronic, in that eye, and in the event of an error of prognosis by a surgeon, and a sympathetic cataract should "form" and cause the other eye to go blind, the same operation would insure an equally successful result. If this new departure in the treatment of cataract will be acceptable to the blind from cataract, it is the coming operation. The next thing will be the cure of squint by decapitation.

McGill University, Montreal.—Dr. G. E. Fenwick has resigned the chair of surgery at the McGill University, owing to impaired health. Dr. T. G. Roddick, one of the editors of the *Montreal Medical Journal*, will be Dr. Fenwick's successor.

STRICTURE OF THE URETHRA IN WOMEN.[1]

BY ELY VAN DE WARKER, M.D.,

SYRACUSE, N. Y.,

FELLOW AMERICAN GYNECOLOGICAL SOCIETY, ETC.

IN this paper I limit the term stricture of the urethra to organic contractions in the lumen of the canal incidental to her sex, or the result of destructive or malignant disease, and not caused by traumatism. In a surgical sense it is the same condition that we define by this term in the male. I find it necessary to thus limit the disease because the affection is supposed to be so rarely found in women that all manner of causes have to be enumerated in order to explain its presence. In the two most recent and elaborate monographs upon the subject, that by Fissiaux [2] and by Herman,[3] all manner of accidental conditions are invoked to explain the condition. When the causes of urethral stricture in women are reduced to two, specific urethritis and traumatism principally (Fissiaux), it will be clear to anyone who studies it independently and free from the unfortunate bias of the authors, that this method simply perpetuates the prevailing error concerning it.

There are certain reasons why organic contractions of the anterior urethra in woman should be expected as the outcome of her functional life. If we examine the external genitals in women of various ages, some of the most marked changes will be presented by the picture of the urinary meatus and the urethral prominence. What in the virgin is small and compact, becomes enlarged in the middle-aged married woman, so that it projects forward between the nymphæ and forms a large, rounded mass bulging downward into the vestibule. The urinary fissure has become irregular, with overlying flaps of the external mucous membrane, unilobed, bilobed, or trilobed, in every variety of form. These changes may, and do, exist without any functional deviation from the normal.

These alterations are evolutionary in character, and are shared in by the other external genitalia. The gland of the clitoris has become greatly enlarged over the virgin form and its prepuce elongated; the nymphæ have increased many times in breadth and thickness, and project beyond the commissure of the pudendum, and the myrtiform bodies occlude the vestibule. That the functional activity which is the source of this evolution may easily pass beyond the normal, is proven by the frequency that stricture of the urethra, or condyloma, angioma, caruncle, and irritations are found.

In the sexual act the urinary meatus and prominence are as much exposed to friction and contact as the urethral opening in the male. These organs in one sex have no exposure to morbid causes that are not equally shared by the other, aside from gestation and pregnancy, which, speaking mathematically, is a plus condition as against woman. The practical outcome of this is that the woman who has not, at some period of active functional life, suffered from urinary distress, is very rarely met with; and, further, I will boldly assert, what every man who faithfully follows my method of urethral exploration will confirm, that urethral strictures, or contractions sufficient to cause symptoms, are as frequently found in women as in men. I express this opinion in no spirit of arrogance or undue self-assertion, but I shall expect every man who offers an opinion to the contrary, other than what may be said hastily in debate, to do so only after he has applied to the study of this subject the modern and approved methods of urethral exploration. He must abandon his authorities and their text-books, which have nourished a most absurd error, and study this matter for himself from the general surgery stand-point. In the event that there may be some among you who have not examined the literature of the subject, but who may wish to know what gynecological authors have to say about it, I can well afford to give the brief space that this requires.

Thomas, in his fifth edition, does not mention the subject. Emmet says that it is rare except as the result of violence. Among older English writers Churchill says: "My own experience does not qualify me to speak as to the frequency of organic stricture of the female; it cannot be very common, or I should have met with it. But I have met with two cases which I suppose to be spasmodic stricture;" and which cases he relates, and which were evidently cases of hysterical retention. West, McClintock, Sir C. M. Clark, Barnes, Baker Brown, Tait, do not mention the subject. Graily Hewitt says it is rare compared to the other sex, and dismisses it in six lines. The later French authors do not give it any mention, so far as I have examined. The elaborate and painstaking German authors ignore the matter. Even Winckel, in a special treatise on the Urinary Organs of Women, in the "Handbuch der Frauen-Krankheiten," gives it no consideration worthy of the name. Coming to more modern times in English literature, we find Hart and Barbour, Mundé, Goodell, Brown, pay it no attention. In the ambitious monograph of Herman, already referred to, and which aims to be scientific, the matter is very inadequately treated, and in a manner which proves that the author has neglected to apply to his investigations the methods of modern urethral surgery; while the paper of Fissiaux, so far as it advances our knowledge of the subject, might as well have been written a generation past. In the "American System of Gynecology," our own Baker starts out with the remarkable statement that stricture of sufficient degree to give rise to urinary symptoms is rarely met with. It is very evident from this that I have a fair field all to myself, as negative evidence never yet proved anything. The mysterious part of the matter is how such a mass of negative evidence was ever able to group itself about a subject so easy of demonstration as this. The mystery is cleared up when we come to examine Skene's book on the "Diseases of the Bladder and Urethra in Women."

Dr. Skene gives more importance to the lesion than any other systematic writer, by admitting that it occurs often enough to demand attention. "The form of stricture that will most frequently come under your consideration," he says, "will be a contraction of the meatus urinarius, produced in many cases by the too liberal use of caustics in the treatment of abnormal growths at the lower end of the urethra, or from vulvitis." It is in relation to the method of examination directed by Skene, who simply follows in the footsteps of his predecessors in a sort of traditional way, wherein lies the error. He directs that the passage be explored with a sound, using

[1] Read before the Section on Obstetrics and Gynecology, American Medical Association, at Nashville, May 22, 1890.
[2] Annales de Gynécologie, January and March, 1879.
[3] Transactions of the London Obstetrical Society, 1887, p. 27.

one so large that it will not pass the stricture, thus locating it, and then by using a sound that will pass through it the extent of the obstruction may be known. If a surgeon writing upon male stricture were to direct such a method of exploring the passage, there would be very few strictures of large calibre, as Otis calls them, that we would ever know much about.

It is by methods such as just described that the period of error has been prolonged. Now, there was a time within the memory of many of us when it may have been said that, in an exact and scientific way, we knew very little about stricture of the male urethra; and yet, concerning this, careful instruction had been given for generations. There came, however, with the use of instruments of precision, a period of more exact examination, which not only gave a more perfect, but a far wider, range of knowledge. In this way an abnormal state was all but discovered and its outcome given its due value, for previous to this period strictures of large calibre were, if known, given no practical importance. Previous to this period the general surgeon gave about the same instruction concerning exploration of the male urethra that Dr. Skene has given for that of the female. It cannot be disputed that, so far as stricture in women is known and treated, it stands to-day where the surgery of the male urethra did a generation ago. I date the knowledge of strictures in the male, of large and small calibre, their number, location, and extent, their consistency and dilatability, together with the calibre of the passage yet in a normal condition, to the invention and general use of the exploratory bulbs and urethrometer. Previously they were simply able to say that a urethra was strictured provided the contraction was small enough.

If we trust in urethral exploration, in women, to the sound, we simply learn that we have to deal with a narrowed passage, and we overlook strictures of large calibre entirely; whereas, if we explore with the bulbs we learn not only all that the sound can reveal, but also the extent, number, and location of the constricted points, their firmness and dilatability, and the differential diameter of each.

Some attention has been given to the question, What is the normal size, or lumen, of the female urethra? I do not understand how a solution of this question can throw any more light upon its stricture than a knowledge of the average diameter of the vagina would aid us to an understanding of atresia of that passage. The question is, not the diameter of the passage, but, is it free from disease; are there no contracting bands or inflammatory deposits that diminish its size, be they large or small? In the male urethra Otis has tried to make an average of this kind of practical importance as a guide to the depth of an internal urethrotomy in a given size of the pendent organ, but I believe few surgeons cut according to Otis's table now. Those that I have seen do it generally incised more extensively than was necessary, especially at the meatus. The accessibility and exceeding dilatability of the female urethra precludes the necessity of internal urethrotomy, and there is even less need here than in the male to establish a law of average. It is interesting, and it may have its usefulness, to know something about the average normal. Dr. Herman, in the article referred to, makes an attempt in this direction.

Tabulation of Dr. Herman's Measurements.

Hegar's dilators.	Equivalent in English scale.	Equivalent in French scale.	Number of persons examined.
No. 7.....	12	22	55
" 8.....	14	25	11
" 9.....	17	29	21
" 10.....	18	30	15
" 11.....	Not given.	Unknown.	6
" 12.....	"	"	1

Dr. Herman employs an instrument that cannot be taken as a comparative standard like those made upon the French scale, which are not arbitrary numbers, but express millimetres in circumference. For this purpose he uses Hegar's dilators, which he describes as "cylindrical rods pointed like the small end of an egg," which must be conically pointed sounds. Even in the use of these imperfect instruments he used so much force that on several occasions he "produced slight lacerations of the mucous membrane."

The conclusion is that in most cases the healthy female urethra will admit a No. 17 catheter, and nearly all cases a No. 14. In the above table the equivalent in the English scale is approximated upon the American, and I assume that there is no material difference. It is very evident, I believe, that beginning in the above table with Hegar's dilator No. 9, the observer used a dilating degree of force, as the fact of bleeding mucous membranes proves. Had he used a urethrometer or the exploring bulbs, the error of using too much force would have been avoided and his measurements would have had scientific value. This author makes gonorrhœa a very frequent cause, a fact that was overlooked by Winckel. He also regards the urethro-vaginal cellular tissue the homologue of the prostate gland in the male, from the fact that in aged women this septum is thickened and indurated, and thus causes narrowing of the urethra. It is difficult to follow Dr. Herman to such a conclusion, and I believe that the majority of observers will dissent from such a comparison. If it were necessary to imagine such a homology, function and situation would suggest the vulvo-vaginal glands. I believe, on the contrary, that the urethral narrowing in aged women is due to the senile involution to be observed in all the genito-urinary apparatus of the sex.

In my own observations to test the calibre of the normal urethra, I noticed the liability to error from the extreme dilatability of the passage when in a healthy condition, an error more difficult to guard against in using the urethrometer than the bulbs. In the following table the measurements were made by the careful introduction of the bulbs, using no force that could put the tissues upon the stretch.

No. of cases.	French scale = millimetres in circumference at meatus.
20	23
18	24
24	25
9	26
18	27
16	28

This does not express the size of the urethra, but rather that of the meatus, at which point there is a slight narrowing. Beyond this point the measurements were taken by the urethrometer, and the increase in the calibre was represented by 1 to 3 mm.; but if the screw of the instrument was slowly turned, thus applying the dilating force gently, one or two divisions of the scale could be added to the above without any discomfort to the woman. For this reason measurements must always lack the exactness that insures scientific value, except for those made at the meatus. Bulbs larger than 29 F., I found, would not pass the meatus without dilating force, except in cases in which appearances indicated a morbid condition of the part. In my measurements every case in which blood followed the bulb or urethrometer was rejected as being in a morbid condition, or as having an excess of force used in the manipulation. There is not a case represented in my table that the measurement would exclude the idea of stricture, or contracting bands, that is, the stricture of large calibre. This at least has been my experience, but this morbid condition is indicated by urinary symptoms more or less constant, or recurring at long intervals.

Several of the writers who give the subject any attention at all appear to derive their standard of comparison from stricture in the male. To a certain extent no comparison is possible. Except as the result of traumatism, the

impervious urethra and exceedingly narrow stricture is not met with in women, but is often met with in men. In connection with an exceedingly crude method of examination, it is this standard of comparison which has so generally led gynecological writers astray on this subject. Further, a narrowing in men that will cause but a slight diminution in the current of urine, never retention, and but rarely dysuria, will produce all of these symptoms in women. I believe this to be the true distinction to be made between the sexes in the symptoms of stricture. Women are exposed to all the etiological conditions that men are, plus a few others incidental to their sex, but these in no way contribute to what may be regarded as sexual differences in symptoms. From whatever cause, retention, incontinence, dysuria and strangury are symptoms much more frequently met with in women than in men, and in consequence slighter pathological changes will cause more active disturbance in the former. If strictures of large calibre in men have the pathological importance that such an accurate observer as Dr. F. N. Otis assigns to them, strictures of a like character have more serious import in women. What Civiale, in 1850, says of male stricture, "that the slightest obstruction in the urethra is able to produce the gravest symptoms," is true with enhanced force in women.

It is not necessary to reason any further from analogy. There is an established method of practice that will bear out the truth of my argument. A long-established treatment of dysuria in women has been by forcible dilatation of the urethra, an operation usually made with the finger of the operator. I have so treated these cases of painful urination many times; sometimes with success, at other times with failure. It was difficult to explain the contradiction in results. I have now learned that when I have succeeded in curing my patient I had to deal with a stricture of large calibre—in other words, I had treated a stricture by what, in the surgery of the male urethra, is termed divulsion. Since I began habitually to examine the urethra with the exploring bulbs in all cases with urinary symptoms, I have never made the operation of forcible dilatation except I wished to examine the cavity of the bladder with the finger. In doing this operation in dysuria I have frequently felt the narrow constricting bands, but without really understanding their nature until I had studied the condition of the passage after the manner of Otis. It is impossible to detect strictures of this size with the sound, as resistance is at every point alike, and from the size of the sound that you are able to pass it does not appear that any stricture is possible. Free as was the opening of the urinary passage, the widely dilatable constricting bands were sufficient to keep up a constant fret of the mucous membrane. I have found these obstructions in urethras that would admit a 28 to 30 F. sound with but very little force, and followed by only a few drops of blood. In exploring, it is well to remember that it is always more easy, as well as less painful to the patient, to introduce a large sound than it is a large bulb. This constant condition of urethral irritation in this group of cases constitutes, I believe, a sexual trait in the different reaction of strictures of this character in the sexes. That which causes frequent and painful micturition in women, and greatly disposes to spasmodic retention, will, as a rule, produce an intractable catarrh in men when situated in the penile passage.

It is remarkable how sensitive the bulbs are in detecting and locating stricture of wide lumen. Sometimes the constrictions are arranged in groups, and a No. 24 or 27 F. bulb will slip along in a series of jerks that offer but little resistance to the hand; but more usually one or two obstructions are found from the middle to the outer half of the passage. The lumen of the normal female urethra is not the same throughout its length. It is contracted toward the meatus, expanded in the middle portion, and contracts again toward the bladder, as may be demonstrated by the urethrometer. One must not, therefore, allow error to occur from the introduction of a too large bulb, which would move with more freedom at one portion of the urethra than another. With one that moves with but little force, the sensation of meeting one of these obstructing bands is so characteristic that there is but little danger of error. They differ in one important particular from obstructions of the same diameter in the male. In women they occupy but a small space longitudinally of the passage, while in the male half an inch to an inch is sometimes involved. All the symptoms evoked by strictures of more contracted forms are observed in those I have been describing. I know of no differential symptoms by which to distinguish the different degrees of contraction. The gravity of the symptoms does not appear to depend upon the extent to which the lumen of the passage is encroached upon, but rather upon the degree of the irritation existing.

Symptoms of functional disturbance due to stricture have their periods of exacerbation and intermission, so that the patient will give a history of frequent and painful micturition, with intervals of relief of a duration of days, and even weeks. Oftentimes the patient rises in the morning in a comfortable condition, with a renewal of the urinary symptoms toward the latter part of the day, especially if she has been much upon her feet, the disturbance lasting well into the night. The power of control is sometimes impaired, the patient being obliged to promptly respond to the inclination, otherwise there will be an involuntary escape of urine.

The form of stricture that I have most frequently met with, and one that produces the most acute symptoms, is the annular stricture of the meatus. It is a firm ring situated at the verge of the opening, and ranges in calibre from 13 to 20 F. It offers quite a solid resistance to the exploring bulb, which has sometimes to be pressed against the ring for a moment before it yields, and what is even more characteristic, presents about an equal resistance to its withdrawal. Some are of large calibre. I have noted one of 23 F. in which the urinary symptoms were very urgent, and which totally disappeared on the passage of sounds with very slight dilating force. The resistance offered to the withdrawal of the bulbous sound, both in the annular stricture at the opening and in obstructions farther up the canal, is one of the most characteristic sensations to the touch presented by these delicate instruments. The treatment of these strictures at the meatus is quite painful, and cocaine ought to be used. In a very few instances I have divided the obstruction upward, but this plan gave no special advantage except in relieving the painful stretch at each passage of the sound.

Very small strictures near the meatus, but not involving the opening—the analogue of what we so frequently meet with in men—I believe are quite rare. In women such an obstruction nearly always involves the meatus. I recall one such case in which the meatus received with difficulty a No. 19 F. bulb, and a firmer contraction half-an inch beyond. The subject was sixty-two years of age, the mother of several children, and had suffered several years from difficult and painful micturition. In this case I divided the strictures, as dilatation was painful even under cocaine. From the thickened and inverted prepuce, the hypertrophied right nympha, with its hardened and corrugated surface, and the general pigmentation of both nymphæ I suspected long-continued masturbation. A long time after the patient confessed that such was the case. This was interesting, as the urethra of this woman presented about the same condition met with in men who have long been subject to this vice.

Persistent retention, due to the mechanical obstruction as a symptom, I have not often met with. I believe that I would better express myself to substitute retarded flow for retention. In one case in which a 16 F. bulb passed the meatus with difficulty, the flow of urine was very slow in starting, and the bladder was slowly emptied, with a small, reluctant stream. In this instance, before any ex-

ploration or stretching, the obstruction offered an opening not to exceed 12 F. to the flow of urine. This woman had had gonorrhœa about ten years previous to my treatment. If one looks for symptoms of mechanical obstruction in stricture of women, I fear that it would be very misleading. Therein lies one of the obstacles to the general recognition of this condition in women. As a sex, she is so continually subject to urethral and bladder symptoms, but without other indications of stricture, that the condition nearly always meets with some other explanation. What in man would inevitably lead to a urethral exploration, even on the part of a very ordinary surgeon, is never made in women, except in cases of exceptional severity.

Another condition sometimes met with at the meatus is what has been called eversion of the mucous membrane of the passage. It is very troublesome and difficult to cure. This is, in my opinion, simply a form of stricture. Cases so treated have made prompt recoveries. Its prototype in the male is the fusiform stricture of the meatus of Otis. This author states that it is rare in the male, and he applies the term congenital to it. In this sex the condition is not revealed except as the result of exploration. In women, however, it is not rare to meet with a rolling out of the mucous lining which presents at the meatus as a red irritable margin. When a full-size bulbous sound is introduced, the protruded mucous membrane is pushed before it, and the resistance to its introduction ceases when the bulb is pushed through the ring. On withdrawing the sound its point is caught by the ring of mucous membrane, which is pulled out to its full extent, thus offering considerable resistance to the withdrawal of the bulb.

The point which I wish to impress is, that this is essentially a stricture. Those of you who have treated the condition know how disposed it is to return even after the margin is pared or cauterized away. I believe that it is explained by the existence of an annular stricture at the meatus and a subsequent dilatation of the urethra behind it. Of course, I do not allege that this may not occur from dilatation of the urethra without stricture; but the diagnostic use of the bulbous explorers demonstrating the obstruction at the meatus puts the pathology beyond doubt. With or without excision of prolapsed mucous margin, permanent cure may be attained by gradual dilatation with the sounds. Two cases of this condition, both in middle-aged women, were cured by relieving the stricture at the meatus, with cure of severe urinary symptoms. In old women, in whom it is more frequently found in connection with annular stricture of the meatus, its cure is practically impossible without cure of the stricture.

I do not propose to take up your time with the detail of illustrative cases. The proof of the matter is so simple to everyone who will provide himself with a set of exploring bulbs, and habitually employ them in every case that presents with urinary symptoms, that I do not believe I can make my case stronger with the history of cases, as I urge all to test the accuracy of my statement. In the treatment of stricture the bulbs are of course not used. I make use of graduated steel sounds, the same that I used when in general surgical practice to treat male stricture. The action is twofold—to dilate gradually and to cause the absorption of the constricting exudate, and that latter end is not attained by sudden and forcible dilatation. The treatment, made two or three times a week, extends over a considerable length of time; but the relief given to the patient early in the treatment is very satisfactory. As dilatation of the urethra is no more important than the absorption caused by the passage of the sounds, it implies a more or less prolonged treatment.

The use of electricity as a treatment I have not had any experience with. Fissiaux states it has given good results at his hands, but I have found the use of graduated sounds so satisfactory that I have not been tempted into new ways. I hold that electrolyzing the sensitive female urethra is a very painful method, and that it will not give speedier or more permanent results than dilatation.

In conclusion I again urge the employment of the exploring bulbs in all cases of dysuria, with the conviction that those who will faithfully follow my methods, earnestly seeking for the truth, will find ample verification of what I claim concerning the frequency of stricture and the important part it plays in the disabilities of women.

GASTRO COLOSTOMY.[1]

By W. M. POLK, M.D.,

NEW YORK.

On March 31st, this year, I admitted to my ward at Bellevue Hospital a female patient who gave the following history: She was forty-eight years of age, had come of healthy parentage, her birthplace being Ireland. She had given birth to eight children, having been married twenty years ago. Her health had always been excellent until eighteen months ago, when she began to suffer from dyspepsia, with occasional attacks of headache. The dyspepsia steadily increased, and about fourteen months ago began to be associated with vomiting. The vomiting was so great a relief to the symptoms of indigestion that at first she welcomed it, but as time progressed it became so constant as to be a daily occurrence and annoyance. The hospital records state that one year before admission the symptoms became much more aggravated, and since that date she has suffered constantly, having pyrosis, pain in the epigastrium, a most distressing sense of fulness and distention of the stomach after eating, more particularly if the food was solid. Vomiting after meals became now the rule. At first but little came up beyond the food or drink recently taken, but in time, especially of late, a chocolate-colored material has been ejected at the same time, and now it is so abundant as to deeply color all of the vomited matter. The bowels, in the main, have been constipated for the past eight or ten months; the most striking change in the patient's condition has been the progressive emaciation. At the outset of the illness her weight was two hundred pounds; at the time of admission to the Hospital it was a trifle over ninety pounds, showing a loss of about one hundred and ten pounds in about one year. Upon admission the emaciation was only too apparent; there was, of course, a great deal of general debility, but still the patient was able to walk about with comparative ease. She remained in the ward for two weeks before the operation, during which period her story concerning the symptoms and signs of her disease was fully verified. All of her organs were found to be free from disease, with the exception of the stomach. Her symptoms, and the vomited matter, clearly pointed to disease there, but additional evidence was found in the shape of a clearly defined tumor, about the size of a goose egg, situated in the region of the pylorus. The diagnosis of "carcinoma of the pylorus with obstruction" was made. The treatment instituted was as follows: The food was limited to peptonized milk, alternating with kumyss, and each day the stomach was washed out with plain water. The bowels were moved daily by a simple enema. Two days before the operation the stomach was washed out, first with Thiersch's solution, this followed at once by enough plain water to displace the solution. Aided by my associate, Dr. Barrows, and the house staff, I operated on April 16th, all the established rules of antisepsis and asepsis being rigidly followed. The time consumed was just one hour. The abdomen was opened by a four-inch incision between the ensiform cartilage and the umbilicus, following the linea alba. The tumor was readily found, and seen to be in the pylorus. It was fairly movable, resting just to the right of the spinal column. Lifting the omentum, the lower surface of the transverse colon was speedily reached; following the meso-colon to the spinal

[1] Read before the Practitioners' Society of New York, May 2, 1890.

column, the head of the jejunum at the crossing was at once recognized; following it downward some six inches, it was seized and brought out at the wound. Some six inches of gut were then drawn out of the abdominal cavity, care being taken to secure a loop free from traction. A section of the anterior and lower surface of the pyloric end of the stomach, in all about the size of a man's hand, was then drawn out. The entire mass was next shut off from the peritoneal cavity by specially prepared gauze. This was packed around the mass as a whole, inside the cavity, outside the cavity, and at the edges of the wounds. A packing was also made between the coil of intestine and stomach.

Following the suggestion of Weir, the intestine and stomach were then stitched, the one to the other, for a distance of about two inches, the line of stitches running along the gut about a third of an inch from the mesentery, and along the stomach about half an inch from the lowest line of the anterior surface. The loop of intestine was then emptied of its contents by pressure, a return being provided against by the pressure of copper-wire clamps covered with rubber tubing, which had been devised by Dr. Barrows. A two inch incision opposite the mesenteric attachment was then made, and the gut washed out with Thiersch's solution. There was nothing in it besides mucus. An Abbe catgut ring (ellipse), measuring three inches in its longest diameter, armed with eight sutures, three on a side and one at each end, was then placed in position inside the gut, and the sutures passed through the gut-wall about half an inch from the incision, ends and sides. A similar cut was next made in the stomach along a line in direct apposition with the incision in the gut, and about four inches from the pylorus. A duplicate Abbe ring was then introduced and secured as before. The ring sutures were then secured and tied, bringing the openings in the two viscera into perfect apposition. Commencing then at the cardiac end of the line of stitching originally made between the intestine and stomach, this line was carried around outside the rings to within half an inch of the pyloric end of the original stitch-line. There I had to stop because of the difficulty experienced in following the proper line for the outside stitches. It had been thrown too far under to be easily reached. I therefore stopped at the point stated, trusting to the action of the rings alone at that point. To recapitulate: I succeeded in covering in the line of apposition created by the rings throughout the entire circumference some half an inch upon the pyloric aspect. The gauze packing, which had proved entirely efficient, was now removed. All the parts were carefully cleansed, and the viscera replaced in the peritoneal cavity. Care was taken to place the region of anastomosis in the most favorable position to avoid traction. The wound was then closed by a double line of sutures—catgut for the peritoneum, and silk for the remaining tissues, being used. The patient's condition during the operation was excellent, but she recovered from the ether very slowly, giving evidence of a good deal of after-shock. This passed off during the night, so that by the following morning she was in a very fair state. She remained in this condition for two days, when she began to freely vomit a chocolate-colored material with a marked cadaveric odor. I then resumed the irrigations of the stomach, using plain water. As they gave her much relief, they were continued at intervals of twenty-four hours, the third and fourth days. She died on the fifth day. Rectal feeding was begun at the close of the operation, and was practically continued up to the day of death. Feeding by the mouth was begun fifty-two hours after the operation, but was stopped in twelve hours, owing to the vomiting. The substance used was peptonized milk, and the amount was one ounce every two hours. The general condition of the patient, considering the nature of the case, was very satisfactory until the beginning of the fourth day. The persistence of the vomiting, together with the nature of the ejected material—it being still deep chocolate color and oppressively cadaveric in odor—showed that a fatal ending was probable. Great feebleness supervened, and the patient steadily sank. The temperature never went above 100° F. until a few hours before death, and the pulse never went above 116 until within twenty-four hours of death. The respirations remained below 25 until the pulse began to mount up above 120, then they rose to 30. On the fourth day I removed the dressings and found that there had been a feeble attempt at union in the abdominal wound. The lower half was gaping between the stitches, and from this portion a watery discharge was exuding. Half an hour after death the wound was opened. As the silk sutures were removed the cut surfaces fell apart. The catgut had been partially absorbed, and there was non-union of the peritoneal surfaces. Practically there was no union of the abdominal incision. The visceral wounds were examined *in situ*. At the cardiac end of the region of anastomosis there was an opening between the stomach and intestine, which extended to about one-half of the circumference of the rings. Protruding through the centre of this opening was the end of the intestinal ring. Throughout the remainder of the circumference of the rings there was the feeblest attempt at union. The best union was at that portion which, as said before, had been left uncovered by the outer protecting line of suture. In fact, the same feeble attempt at union found in the cut in the abdominal wall characterized the reparative process in the entire region of anastomosis.

Opening the stomach the following conditions were seen:

The cardiac half of the ring was wholly digested, no vestige of it being left; all of the ring sutures at that end, three in number, had pulled out, the others held firm; the stomach contents were similar to the vomited material; the constriction at the pylorus was so great that the opening would scarcely admit a goose quill.

The interior of the intestine presented nothing of special note. This ring was intact, but twisted into a figure 8, one end projecting from the wound as already described.

In presenting this case to the Society I wish to bear testimony to the comparative ease with which the operation can be done, and, in this case, to the readiness with which the upper end of the jejunum was found. I used the meso-colon as a guide, following its under surface directly down to the great vessels, when at the crossing I readily appreciated the beginning of that portion of the small intestine in question. To follow it far enough to obtain a free loop was then a matter of a few seconds. The wisdom of Dr. Weir's procedure, namely, before making either opening to stitch what would be, after the completed operation, the under mesenteric edge of the incised intestine, to the stomach, just below the point at which that organ was to be opened, was clearly proven here, because, after the rings were tied in position, all the under-region was practically beyond reach. As it was, so soon as the rings were tied down all that remained to be done was merely to continue the outside protecting suture from one end of that originally placed around the rings to the other, thus completely covering them. In this case, however, as has been stated, owing to an error in calculation, the protecting suture was deficient for about half an inch.

The difficulty experienced in rectifying the error served the purpose of accentuating the importance of the preliminary stitching. The unfortunate ending of the case was clearly due to the lack of union, and that seemed to be due to the patient's general state. The sequence of events was non-union, or at least very feeble union, digestion of the cardiac half of the ring in the stomach, and loosening of all the ring sutures of that section. This loosening was aided no doubt by the disturbances of vomiting. In reviewing the case from my standpoint, I can detect but one flaw, and that was the omission of scarification of the opposing serous surfaces, as suggested by Secur. In future I will do it.

I followed along the jejunum until I got hold of a portion which could easily be brought out and kept out of the abdominal wound without any difficulty whatever, so that the trouble could not have arisen from not going far enough down; there was no traction. If the anatomical difficulties could be overcome, it would be much better to make the anastomosis on the posterior wall of the stomach, but I agree with Dr. Weir that this would be very difficult. The rings were made according to Abbé's suggestion, were completed two days before the operation, and were kept under pressure until the operation. The sutures were fastened to but two of the strands of catgut in the rings.

HEMORRHAGES IN THE NEW-BORN.[1]

BY EDWARD L. PARTRIDGE, M.D.,

ADJUNCT PROFESSOR OF OBSTETRICS, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; PHYSICIAN TO THE NEW YORK AND THE NURSERY AND CHILD'S HOSPITAL; ASSISTANT PHYSICIAN TO THE SLOANE MATERNITY HOSPITAL.

THE relation of the following case will serve to introduce the subject of this paper, and is as follows:

Mrs. T—— was confined at term, on November 14, 1889, the child being born at 10 P.M. Labor was normal; the child, which was her fifth, being a boy of average size and development. The placenta was normal. No hemorrhage took place, though in this, as in previous labors, a marked disposition to uterine inertia was observed. On the following morning, twelve hours after birth, the nurse called attention to the character of the child's urine as indicated by the appearance of the napkins. These, I observed, were deeply stained. There was not present the pinkish appearance caused by the presence of urates, nor an ordinary staining as by bile coloring-matter, but a staining similar to the latter, except that it was deeper and more reddish. The child had not acquired the cutaneous capillary congestion so common on the day after birth, but had a color which was a compromise between a bluish pallor and slight jaundice. Sometime during the night of this day (twenty-four to thirty hours after birth) hemorrhage at the umbilicus began, and early the following morning, on a hasty summons, I found the clothing of the child soaked with blood. So much bleeding had occurred that the outer garment had an irregular, stained, and wet area six inches in diameter. On undressing the infant the belly-band and linen about the navel were found so saturated that blood could be squeezed from them. The cord was normal, and the bleeding was taking place throughout the circumference at the junction of skin and cord, the latter having begun the usual separation. The child was strikingly yellow. I have never seen anything like it in the jaundice of the new-born. The lips were pallid, with a slightly livid hue. A dressing of Rohland's styptic cotton, with compress, was placed with care on the bleeding surface. In the next twenty-four hours three more dressings of the same character were required, owing, each time, to a saturation of previous dressing and of compress. The bleeding was of the nature of a steady oozing, the hydræmic character of the blood being shown in lack of coagulation and in the watery appearance of the blood-stains. Two slight scratches on the child's face kept up a continuous oozing, as well as a scratch in the external auditory canal.

On the following morning removal of dressings was again required, owing to bleeding. The separation of the cord was progressing, a slight arterial pulsation in the bleeding surface, and the escape of blood was more rapid. The navel was transfixed by pins inserted at right angles a quarter of an inch beneath the border of the skin, and a ligature applied with moderate tightness—sufficient to stop bleeding, and with the hope that a new solution of continuity, by pressure of the silk, would not be effected too soon. The child was more deeply jaundiced and had lost his plumpness. He nursed for about ten minutes at infrequent intervals. The scratches steadily oozed, and the movements, which by this time should have been lighter, were dark, and possessed an offensive somewhat putrid odor. Twice during the day it was necessary to tighten the ligature to stop bleeding—on the last occasion it being tied as firmly as possible.

From this time no serious bleeding from the navel occurred, though some leaking took place, and blood continued to escape from the scratches in the face and from the ear for the next five days. The movements continued tarry and offensive for the same length of time. The child kept its deep jaundice, with bloodless lips and wrinkled skin. He cried feebly and was fed breast-milk and brandy by spoon, as he was unable through weakness to nurse. The cord was dressed with iodoform, and was slightly offensive, though as much as possible beyond the ligature was removed. There was considerable superficial œdema of the abdominal wall, without an erythema, as the result of the pins and ligature, but at no time any sign of peritoneal inflammation.

On the seventh day the child nursed a little in a feeble way, the movements were lighter, and the scratches stopped bleeding. Until this time the urine stained the napkins with the dark, reddish color. When quiet one would have readily supposed the child to be dead, from the pallor of lips and of scars of the scratches. The skin resembled that of the deepest yellow of an advanced case of cirrhosis of the liver.

On the ninth day the stump of cord separated without hemorrhage. From this time there was a slow but steady gain in every way.

By December 1st, the sixteenth day, the child was nursing very well, had much less jaundice, exhibited a fair degree of strength, had light-colored stools, and urine normal in appearance. The navel was now nearly healed.

The previous children in this family have lived, though at times showing rather marked anæmic tendencies.

Hemorrhages in the new-born are not of very infrequent occurrence, and an effort is made at the present day to accomplish some classification of them based upon cause.

The blood itself and the blood-vessels have received chief attention; while inherited disease and diathesis have received their share of study.

During the last six years, among 1,166 infants born at the Nursery and Child's Hospital, 11 have presented, within the first ten days of life, hemorrhages varying in character and gravity. Death occurred in seventy-five per cent.

At the Sloane Maternity Hospital, from 850 infants born, there have been 14 cases of this nature, with a mortality of over sixty per cent. (1½ per cent. in 2,000 cases). The result of investigation of family history among hospital patients is never very satisfactory. Circumstances illustrating family hemorrhagic tendencies would be dramatic enough, however, to hold attention, and it would seem that in a matter requiring such simple observation and information facts supporting hereditary disposition would be discovered if they existed.

In no instance from over thirty cases which have been known by me have I obtained history of hereditary influence.

In the writings of those who consider cases of hemorrhages in the new-born the word "hæmatophilia" is used to designate the condition in them however, though we do not find that reports of these cases usually afford evidence of this inherited diathesis. This certainly cannot be said of spontaneous hemorrhages in older children and in adults. The term hæmatophilia, then, if it implies the hereditary influence, is hardly applicable to the very great majority of hemorrhages in the new-born.

The tendencies to hemorrhages in families of bleeders is rarely shown before the second, and most commonly after the fifth, year. In infants born in such families

[1] Read before the Practitioners' Society of New York, May 23, 1890.

hemorrhage from the umbilicus after sloughing of the cord is very rare

In looking for the cause, or causes, of hemorrhage in the new-born, we thus speedily eliminate the hereditary nature. Were these hemorrhages limited to certain localities our attention would be toward special parts or organs. Umbilical hemorrhage would be favored always by the uniform presence of a solution of skin continuity at the navel in the new-born, yet in the great majority of instances it is associated with hemorrhages elsewhere. In view of this latter fact we cannot assume a mechanical or a physiological influence from sudden change in the abdominal or liver circulation after birth, when immediate closure of umbilical arteries and vein takes place.

Hemorrhages in the cases which I have seen have occurred from vessels in almost every part of the body, and in almost every organ. I have seen it in its most severe character—and non-traumatic—from conjunctiva of both lid and eyeball; from ears, mouth, nose, vagina, scrotum, beneath the skin in lumbar and gluteal regions, cheeks, abdomen, trunk, and extremities, and, less commonly, in subcutaneous cellular tissue. Hemorrhages from stomach and intestine are rather common, and in post-mortem examinations I have known them to be subpleural and subperitoneal; in the heart and lungs, mediastinum, abdominal and cranial cavities, and four times in or upon the suprarenal capsules.

The condition seems more common in the middle and lower classes, and does not belong to children who appear small and badly nourished at birth. A history of syphilis in the mother is occasionally met with, tubercular predisposition not being noticeable. In the parents of these children we do not find health which could be termed the most robust, however.

In the great majority of cases then—some of which prove fatal from loss of blood and inanition, and some of which recover—in the absence of sepsis and with no hæmoglobinæmia to a degree which could be called disease, we are reduced to find an explanation in primary changes of the circulating fluid, or in the structures of the vascular system.

As the condition of the blood alone cannot account for the hemorrhages, impairment of the vessel-walls must exist.

As having some importance on the etiology, I would call attention to the fact that before birth the child grows simply through the influence of maternal functions. It has not a functional activity of its own. There is no cerebration, and little or no evidence of digestive function. The liver, large as it is at birth, has secreted but faint traces of bile, and the kidneys but little urine. The function of assimilation alone has gone on.

All tissues are embryonic, and so continue, mainly, for a time after birth. It is only when a separate existence has continued for a time that a waste and renewal of tissues have taken place. Before this has transpired, let us say for the first ten days of life, we have tissues of extremely delicate and fragile organization, and we have vascular structures developed sufficiently only for a physiological existence which has not previously required any special influence of nerve-centres or visceral activity in the child. Suddenly, at birth, a new kind of existence is required, and it is significant that after the first ten days of life hemorrhages do not occur. Defective innervation and imperfect performance of functions are not uncommonly seen in the beginning of infantile life, and a very brief interruption of the nutrition of blood-vessels is known to be sufficient for transudation of their contents. We can readily believe that these delicate tissues may be liable to degeneration which will be disproportionate to regeneration, increasing the liability to hemorrhage.

If hæmic changes are added, or some dyscrasia present, obtained through lack of parental vigor, the liability is increased.

In another class of cases of hemorrhage in the new-born, illustrated by a small minority, we find an altered blood state as the chief determining cause, and associated with the bleeding we find, to a striking degree, the occurrence of jaundice and of urinary signs of disease.

Here the pathology of to-day has endeavored to establish a germ origin, and special study of the blood has been already undertaken. For a long period an occasional case, associated with a remarkable degree of jaundice, has attracted attention from unusual malignancy, and from a knowledge of an occasional relation of syphilis to infantile hemorrhages we have formerly contented ourselves with falling back upon that disease as the cause, or have been satisfied with the diagnosis of acute fatty degeneration.

Then attention noted the association of fatty degeneration with loss of hæmoglobin. Finally, hæmoglobinuria was noted as the urinary condition, associated with deep jaundice or cyanosis, with an altered blood condition, and with hemorrhages in the new-born.

Hæmoglobinuria as the result of corpuscular degeneration and a solution of hæmoglobin in the blood plasma is known to have its origin through the introduction of various agents into the system, such as naphthol, pyrogallic acid, arseniuretted hydrogen, chlorate of potassium, anilin, and others. Extensive burns of the surface and transfusion of blood are also productive.

The fœtus is not much exposed to the introduction into its system of the agents first mentioned. Disease of the placenta (a condition often noted in connection with the birth of the grave cases of infantile hæmoglobinuria) would, through degeneration of placental villi and tufts, readily afford a direct communication between maternal and fœtal blood, and an actual introduction of alien blood, with any morbific principle it may contain, into the blood of the fœtus.

Hirst has reported an interesting case of acute hæmoglobinuria and hemorrhage in the new-born, in which he obtained cultures from the blood before and after death, as well as from the spleen, the product being regarded as the streptococcus pyogenes. Also portions of spleen, lungs, liver, and kidney showed presence of micrococci under the microscope. In this case the mother had been obscurely ill just before delivery, the placenta being "slightly calcified." It was thought that "some overlooked focus of suppuration in the mother's structure produced general fœtal metastasis and hæmic infection in the infant."

Winckel has described endemic hæmoglobinuria in the new-born, giving a report of twenty-three cases with nineteen deaths. The disease presented the symptoms of jaundice, cyanosis, and hemorrhages. The post-mortem appearances were the hæmoglobin streaks in the renal pyramids, swelling of Peyer's patches and mesenteric glands, and fatty visceral degenerations. The cause in this group of cases was not made out, but Winckel leans strongly to the view of germ-infection.

A few observers have described isolated cases, among them Vogel, who has observed instances in which malignant icterus in infants coexisted with puerperal septicæmia, and who believed the two conditions to be due to a common infectious element. Besides the case which I have related I have seen two others which were fatal. In them there was deep jaundice, dark-colored urine, and, on autopsy, blood which showed little or no coagulability.

It is evident that there is a field for investigation in acute hæmoglobinuria of the new-born. The much more common origin of the cases in hospital rather than in private practice may be noted, and it would be the former class of infants which would be most exposed to septic infection, which, perhaps, produces the disease. In the more numerous class first mentioned, unattended by hæmoglobinuria, infection may be a factor in their causation, for septic infection does not necessarily run a grave course. While I am not sure to what class the case I have reported belongs, I believe that there was disintegration of the red corpuscles, and that hæmoglobinuria,

suggested by superficial examination of the urine, would have been confirmed by laboratory examination. The only lacking clinical feature was marked cyanosis; yet with pallor from loss of blood, and with the intense icterus, it would not be readily distinguished, particularly in what must have been a comparatively mild condition of blood change, as shown by the child's recovery. There is also a probability that in those cases attended by deep jaundice the dissolved hæmoglobin is converted into biliary coloring matter—bilirubin—giving a yellow rather than a cyanotic appearance to the tissues; the cyanosis so often noted in hæmoglobinuria being known to be due to a conversion of hæmglobin into methæmoglobin, the latter being incapable of carrying oxygen. In the latter event the tissues fail of the reddish, oxygenated appearance, and present the bluish color.

There is an interesting fact, to which Silbermann has called attention, which probably places all cases of hemorrhage in the new-born upon a common basis of hæmatogenous origin to some extent at least.

Between the less severe cases, with recovery, and the very grave and usually fatal cases presenting all the evidence of acute hæmoglobinuria, there is the connecting link of hæmoglobinæmia common to all new-born. Silbermann has found that within the first week of life there is a reduction of about one-third in the number of red blood-corpuscles in all infants, and calls this change a physiological hæmoglobinæmia. This condition, though physiological, is yet of the nature of a very marked hæmic alteration, and associated with the embryonic character of tissues explains, to my mind, the more mild cases of hemorrhage in the new-born. When the physiological blood-change becomes pathological, through the influences we have previously mentioned, and there is added, as evidence of this, hæmoglobinuria and active fatty degenerative changes, we have the grave and usually fatal class as the result.

A consideration of hemorrhage in the new-born would not be complete without an allusion to the occasional appearance of vaginal discharge of blood and mucus in the first three weeks of life, usually about the end of the first week. This continues from three to five days, is moderate in amount, and rarely recurs. The health of the child is not influenced by it. I have seen three cases, the discharge being present behind the hymen, but, as far as I know, no one has ever determined the precise bleeding surface.

Autopsies have shown blood in the uterine cavity, though it is not shown in these reports that these were cases of simple genital hemorrhage. As such genital discharge of blood occurs in female children only, it cannot be due wholly to ligation of umbilical arteries, or to tight application of the abdominal binder, as has been suggested. No satisfactory explanation has been offered for this discharge, which closely resembles menstruation in its duration and method of onset and departure, but which is rarely repeated. Probably, like the turgescence of the mammæ seen in young infants, it has an origin in part through nerve stimulus. There is always some mucus present in the vagina of a new-born child, which would account for this admixture in the discharge, and fragility of tissues would exist, according to my opinion already expressed.

The Urine during Pregnancy.—Professor Tarnier has made public the conclusions of a work by Drs. Laulanié and Chambrelent on the considerable diminution of the toxicity of the urine of pregnant women, particularly toward the end of their gestation. This toxicity is far inferior to that of normal urine, as established by Professor Bouchard. In two experiments out of ten the urine of pregnant women was atoxic. The authors therefore conclude that the organism of a woman toward the end of her pregnancy retains the toxic substances ordinarily eliminated by the urine.

THE PROGNOSIS OF LATERAL CURVATURE IN YOUNG GIRLS.[1]

By V. P. GIBNEY, M.D.,
NEW YORK.

At the request of the Secretary of the Society, a gentleman who is competent to decide on the merits of papers presented to this body, I have made an attempt this evening to discourse upon the above title. I am sure that the practitioner of medicine is always ready to express his views upon the prognosis of lateral curvature. The impression prevails that the deformity is progressive, that a slight curve ends in a hunchback, and that something mechanical must be applied in order to prevent this result. At the outset, then, let me state my conviction that one seldom has an opportunity of observing the evolution of a lateral curvature of the spine. Somehow or other the apparatus we employ or the treatment we suggest succeeds (so to speak) in arresting the deformity. For ten or twelve years, while interne at the Hospital for the Ruptured and Crippled, and while in charge, also, of the Out-patient Department, I had an opportunity of following a large number of cases of lateral curvature in young girls, and the routine treatment was this: Applied a Knight brace, which was made to fit the body as nearly as possible, made of steel, with bands half-encircling the body (the posterior half) from axilla to axilla, from ilio-costal space to ilio-costal space, from trochanter to trochanter, and the terminal ends of these bands, connected by uprights, passing from the axilla down to the trochanter. One or two bars were placed in the middle half, either side of the vertical bearing of the spine, a leather or steel plate passed from one of the posterior bars to the lateral bar, the object of which was to make pressure against the projecting ribs, and this steel framework, properly upholstered, was held in place by canvas fronts. Shoulder-straps were employed to complete the appliance, and we had thus a steel and canvas encasement, which the patient wore by day, removed by night, and reported from time to time, in order to see that a reasonable fit had been secured. In addition to the mechanical appliance thus employed, each patient was instructed to exercise on parallel bars five or ten minutes twice a day, with or without apparatus. The parallel bar exercise consisted in suspending themselves by the arms and hands, allowing the weight of the pelvis and limbs to make a certain amount of traction on the column. No other exercises were employed.

Simple as this treatment was, and crude as it seemed to many to be, I was enabled, at the end of eleven years' residence in the hospital, to express my opinion that I had never seen a complete evolution of a lateral curvature of the spine. That is to say: I had not seen a case in the early stage, where osseous changes were absent, proceed to the development of a marked rotary lateral curve, with prominence of one shoulder, enlarged letter **S** deformity, shortening of stature, and an overlapping of the ilium by the free ribs.

It is true, during this period, while the plaster-of-Paris jacket was so popular, that I read and heard of cases wherein the treatment I have just recorded had been employed, and where the patient stated that the deformity had increased perceptibly, to be relieved only by the plaster-of-Paris jacket. Lectures were held upon our cases. These lectures were reported in the journals, and occasionally some old patient, who had been treated right royally at the hospital, would return to show what a wonderful change had been effected by this new treatment.

In 1884, relieved from hospital duty, I became quite enthusiastic in the plastic treatment of this deformity. I secured, by reason of my long personal acquaintance with many dispensary patients, a large contingent at my clinic. I familiarized myself with the details of the jacket, studied it as I would an art, and after a year or two acquired a fair degree of skill in its application. I

[1] Read before the Practitioners' Society, May 23, 1890.

treated not only my clinic, but my private patients with the plaster-of-Paris corset, and combined with this treatment certain exercises said to emanate from Mr. Bernard Roth, of London. After three years of this kind of practice I was enabled to state that I had seen the evolution of a rotary lateral curvature. So that, in 1887, during the summer, my enthusiasm had suffered such a shock that I decided to abandon the plaster-of-Paris corset as a mode of treatment. During this time, however, I had employed occasionally certain other forms of steel appliances with equally unsatisfactory results. Visiting Mr. Roth, of London, I gathered from him the opinion that medical gymnastics were all that is necessary to prevent deformity, and, in many instances, to correct. This gentleman asserted quite positively that the combination of steel and plastic appliances with gymnastics was a form of treatment which resulted in no benefit; that gymnastics employed once or twice in the twenty-four hours, the object of which was to develop muscles, were counteracted most efficiently by steel or plastic appliances during the rest of the time.

In the fall of 1887 I began the treatment by medical gymnastics, as I had learned it from Mr. Roth, and I am happy to say that the majority of my cases have done well. I do not mean to state that many have been cured, but I do mean to state that in rare instances only has the deformity increased, or have the parents and patients been dissatisfied with the result.

During this long period of eighteen or nineteen years, I have seen a large number of patients who presented a slight degree of deformity, wherein no appreciable increase has taken place even without treatment. In many instances I have recommended an out-of-door life, horseback riding, rowing, and deportment to patients who lived in the country, and I have learned from the family physicians, years afterward, that the deformity had become scarcely appreciable, and that the cases had given them no more anxiety. I have become, therefore, an advocate for an out-of-door life in young girls who were crowded at school, who keep too long hours in any capacity, and who have acquired a slovenly position in standing or sitting.

With the Swedish-movement cure I have had no extended experience. For the past three or four months, however, a gentleman, Mr. Lindhe, recommended to me very highly by Dr. Purdy, of this city, has taken charge of my charity cases at the hospital, out-patient department, and has labored daily with a class numbering about thirty. The movements differ somewhat from those of Mr. Roth, in that more force is employed. This gentleman has consented to bring a number of my patients here this evening and show you his method. The testimony of the parents and girls themselves is that they have improved. The gentlemen present will agree with me that the only way to predicate any results would be to examine carefully with a scoliosometer, and repeat the examinations months or years afterward. The difficulties attending a careful measurement are so great that I have come to rely upon a few salient points in the way of record, and upon the eye in determining the amount of improvement or the reverse. My results, then, are measured in this way.

The foregoing remarks are necessary, I think, to a proper study of the subject in hand, namely—The Prognosis of Lateral Curvature in Young Girls. The family physician is, or ought to be, consulted quite early in any kind of deformity. The deformity now under consideration is usually first observed by the dressmaker. The attention of the parents is called to inequality of the two sides. One shoulder-blade projects a little more than the other; one hip may be higher than the other, and the dress skirt on one side must be a little longer. There is, in a word, a lack of symmetry.

The different methods of treatment discussed are sufficient to encourage the practitioner in the management of his cases. It is sufficient, thus, to be forewarned.

The average physician can recognize an early case of lateral curvature, provided he take the trouble to examine. The following method, I think, will enable anyone to discover a curve, however slight. Let the patient be stripped down to the hips, not the waist-band, but down to the hips; let the skirts be fastened around the pelvis just above the trochanters major; have the shoes removed, let the patient stand in stocking-feet; then let a good light be brought to bear upon the back. Any lack of symmetry can be easily recognized. One wants to note the position of the scapulæ—whether one is on a higher plane than the other, whether one is farther removed from the spinous processes or the vertical bearing than the other, whether one projects farther backward than the other. Examine the tips of the shoulders to note whether one shoulder is higher than the other. Compare the ilio costal spaces, note whether one is deeper, or whether the curve is longer than the other. Finally, the deviation of the spinal column itself, the locality where the deviation occurs, and the projection of the ribs on one or the other side should be noted. A front view can be had, which will enable one to determine any rachitic changes in the sternum or any inequality of the mammæ. In lateral curvature it must be remembered that one mamma is larger than the other, and the larger mamma corresponds to the side on which the concavity of the curve is found. Let the patient now bend forward as far as possible at the hips without bending the knees, and aim to touch the floor with the fingers. This will show the inequality of the chest-walls, will show how much more prominent the ribs are on one side than on the other. One can also note the prominence or the reverse of the spinous processes, and can thus determine quite easily that part of the column where the rotation is greatest. No examination can be complete, however, without measuring the length of the limbs, not only with the tape-measure, but also in an upright position, by placing books of various thicknesses under each foot and noting how much thickness is requisite to equalize the pelvis and to reduce the actual deviation to the minimum. Dr. Morton, of Philadelphia, has a very ingenious contrivance for this, but it is practically the same as the method just mentioned, namely—books of various thicknesses.

With the observations completed, a prognosis can be readily given. I, of course, do not mean to say that the prognosis can be given independent of any treatment employed, but what I mean is this: The physician who has made the examination just described will adopt some method of treatment that will, as a rule, result favorably. The difficulty is not in one's ignorance of what to adopt, but in the lack of interest manifested by the parents or the patient. Again, physicians are so uncertain about the different forms of apparatus that they give their opinion in an uncertain sort of way, and it is not regarded as of much value. The prominence given to athletic sports in general now, for both sexes, I think will enable us to give a better prognosis in our cases. Whatever course of exercises is decided upon, it must be carried out thoroughly. A daily drill is requisite. It is not sufficient to say to the patient, "Go home and exercise," or "Take this and take that." It is important to show the patient how to exercise. If a brace is to be employed, it should be made to fit the patient, and should not be worn at night. If I find a cardiac murmur, I do not prescribe a course of exercises, unless I can direct them myself and know the influence on the organ itself. Such patients I prefer to encase in a steel apparatus.

This deformity, like many diseases, is self-limited. A little twist is developed in the back, one shoulder projects a little more than the other, and a curvature results. The curvature is so slight that it is not recognized, and the patient grows to womanhood without ever knowing that she has a curve. Such instances do occur. They are not frequent, only it is important to know that all curves do not go on to great deformity. In my opinion the greatly deformed cases are the exception. Con-

sidering the number of girls who have one hip higher than the other, or one shoulder more prominent, it is astonishing that we do not have more exaggerated deformities with our present ideas of the progress of such cases. It simply means that a great deal too much stress can be laid upon a slight deformity, while repeated observations will enable one to determine whether it really is increasing or not. If such a patient had been advised to take better care of the health, to cultivate a better deportment, to take every opportunity for improvement of the muscular system, one can reasonably give a good prognosis.

To conclude, then, we see that The Prognosis of Lateral Curvature in Young Girls depends a great deal upon the early recognition of the deformity. It will also depend upon the thoroughness of the treatment employed. If an apparatus is used, it must be made so as to meet the indications and must be worn for a long time, from two to five years. If gymnastics are prescribed, the patient must be taught the different movements, must be drilled in the same after a good knowledge is acquired, and the exercises should be continued at home for a year or two. If it is found that the deformity is very slight and the patient can lead an out-of-door life, and is not crowded too much at school, a good prognosis can be expected if only the ordinary rules governing general health are observed. In the more advanced cases it is not possible to correct the deformity to any great extent. Indeed, it may safely be assumed now that no form of treatment yet adopted is equal to the correction of an osseous deformity. All that we can hope is a better position in standing and sitting, a better carriage, a filling out of the chest more symmetrically, and an ability on the part of the patient to hide the deformity.

A CASE OF ALCOHOLIC CIRRHOSIS OF THE LIVER IN A BOY, AGED THIRTEEN.[1]

By HERMANN M. BIGGS, M.D.,

NEW YORK.

In the early part of April of this year, through the courtesy of Dr. Jenkins (coroner's physician), I performed the autopsy on a boy, aged thirteen, who had died, with the following history: He was found in an unconscious condition at 1 P.M., in an outside water-closet, his absence having been noted for several hours. He was removed to the house, and died a few hours later without regaining consciousness. In the house was found a soda-water bottle, nearly emptied, but still containing a small amount of whiskey. The previous history, as given by the family, was about as follows: When two and a half years of age he had an attack of bronchitis, and was then given whiskey. He contracted at once apparently a taste for it, and its use had been continued to a greater or less extent since that time. He had suffered from most of the diseases of childhood, and had always received whiskey at these times. The family said he was a rather stupid boy; there were few things he cared for, and as he liked whiskey he had always been allowed to have it, and during the last two or three years had taken it almost constantly. He was supplied daily with money, and regularly went to the saloon each day to replenish his supply. He was accustomed to taking from one ounce to an ounce and a half in milk, five or six times daily. Early on the morning of his death he seemed to be well, and went out as usual to have his bottle filled.

Apparently a much larger quantity than usual was taken, and his death was the result, as it was believed, from acute alocholic poisoning supervening on a chronic alcoholic condition. His general stupidity was probably due to the semi-intoxicated condition in which he had constantly been during the larger part of his life. Strangely enough the boy's family was rather superior to those of the ordinary working-classes. His father was a perfectly temperate man, and the other members of the family only drank occasionally and in moderation.

[1] Read before the New York Practitioners' Society, May 2, 1890.

Autopsy.—Subject presented in miniature the picture of chronic advanced alcoholism as seen in old subjects. His face was pale, pasty, and bloated. There was slight œdema of the legs, the abdomen was large and the layer of fat extremely thick. On opening the abdomen the liver extended an inch and a half below the free border of the ribs, and its surface presented the typical appearance of a well-marked hobnailed liver. There was no fluid in the abdominal cavity. The heart was slightly large for the age of the subject and the lungs somewhat œdematous. The spleen was enlarged, rather firm, and weighed 400 grammes. The kidney presented the usual appearances of a very moderately developed diffuse nephritis. The capacity of the stomach was increased and the mucous membrane was thickened and congested, and was covered by a thick, glassy mucus. The brain showed what is familiarly known as a "wet brain." On opening the dura a large amount of fluid escaped, and the meshes of the pia were distended with serum; the ventricles were greatly dilated, and the ependyma was tough, fibrous, and granular.

To return to the liver. The surface was characteristically hobnailed, the elevated portions being of a light yellow color, and the depressed lines between them a bright red. The size was considerably increased, and the weight was 1,430 grammes. On section the tissue was friable and presented the same bright yellow projecting portions with narrow depressed grayish lines surrounding them. The microscopical appearances showed the ordinary changes found in cirrhosis, but the fatty infiltration of the liver, cells was extraordinarily advanced. The amount of newformed connective tissue was not great.

The literature of this subject is very scanty and of recent date. Most authors agree to the comparative rarity of the disease in children.

Two careful papers were published in 1887 on cirrhosis of the liver in children; one by Dr. Howard[1] and another by Drs. Laurie and Honorat.[2] Both of these papers are introduced by quotations affirming the extreme rarity of hepatic cirrhosis in children.

In Dr. Howard's paper Dr. Charles West is quoted as stating that an experience in 70,000 cases of children's diseases has yielded him but 4 cases of cirrhosis of the liver. Henoch has never seen a case, and Dr. Neureuter is said to estimate its ratio to other diseases as one-tenth of one per cent.

Rarer by far are those in which the disease is due to the common cause of its existence in adults—alcoholism. There are but few such cases on record. In a collection of 63 cases made by Dr. Howard (2 of which are his own) only 10 had a history of abuse of alcohol. In addition to these Dr. Norman Moore[3] reports a case in a boy, aged five, in whom hepatic cirrhosis was due to alcohol; and Dr. Wilks reports a case, at eight years of age, in a girl known to have taken gin in quantities of half a pint daily.

The two papers, Dr. Howard's and Drs. Laurie and Honorat's, contain together a series of 78 cases of cirrhosis from all causes. Thirty-three of these are identical, 17 appear alone in the French paper, and 28 alone in Dr. Howard's. Dr. v. Kahlden[4] has gathered the following data from the literature on the subject: As to size of the liver, in 19 cases it was atrophic, in 6 cases normal, in 15 cases larger. As to the age of the subject: 1 child born dead; 3 died first week; 1 died first month; 4 died in three months; 1 died in four months; 4 aged fifteen to twenty months; 3 aged between one and one-half and two years; 2 aged three years; 13 aged five to eight years; 28 aged nine to thirteen years; 2 aged fourteen to fifteen years. Thirty-five were male, 14 female. In

[3] British Medical Journal, April 20, 1889.
[4] Arch. für Kinderheilkunde, xxvi., 402.

34 cases ascites was present; in 23 cases icterus was present.

As to causes of cirrhosis in children other than alcohol: In 7 cases of Dr. Howard's collection a heredito-syphilitic origin was reported. In one case venous congestion was the probable cause. In another there was a white false membrane in all parts of the abdomen enclosing the liver, and this led to the belief that peritonitis may have extended to the capsule of the liver and excited interstitial hepatitis. In 7 or 8 cases the cirrhosis was associated with tubercular disease.

Dr. Legg reports a case of biliary cirrhosis in an infant, due to congenital absence of the bile-ducts.

In about half of the 63 cases reported by Dr. Howard the cause of the disease was not accounted for. Dr. Howard raises the question whether cirrhosis of the liver in children may not in many cases be regarded as secondary to one of the infectious diseases, such as measles, typhoid fever, and scarlet fever. There is, as Dr. Howard admits, no proof of this, but it seems a very probable supposition, and the experience of a few authors furnishes some evidence.

Dr. Crook,[1] and also Dr. Klein, state that they have found extensive acute hepatitis in children who died of scarlet fever. Drs. Laurie and Honorat also seem to regard the various forms of infectious diseases, especially measles, as etiological factors of hepatic cirrhosis in children.

A number of cases of cirrhosis have been reported as having been found at birth. One of them was at the thirtieth week of utero-gestation, and another at the thirty-fourth week. Those cases of congenital disease, and also those occurring during the first year of life, are probably all syphilitic in character. V. Kahlden, in fact, states that all of the cases of syphilitic cirrhosis are congenital, and that acquired syphilis never produces a true cirrhosis.

Tuberculosis and tubercular peritonitis have been associated with cirrhosis in children in a number of cases. Dr. G. N. Pitt[2] reports two cases of hepatic cirrhosis in children, with tuberculosis of the liver and tubercular peritonitis.

Dr. Norman Moore states that he has seen cases of cirrhosis indistinguishable from alcoholic cirrhosis in chronic tubercular peritonitis.

The known causes, then, of the disease in children, seem to be nearly the same as those assigned as having a causative agency in its production in adults, viz., alcohol, syphilis, and, in addition, possibly tuberculosis and tubercular peritonitis, and a general tendency to connective-tissue formation.

There remains, however, a very large proportion of cases—nearly one-half—in which these causes do not account for the occurrence of the disease. It seems probable, however, as has been suggested by Klein, Crook, Howard, and others, that the acute infectious diseases may occasionally produce the disease, and finally, that a stimulating diet and the products of faulty digestion may also occasion interstitial new formation in the liver. If we admit, as is probably the case, that the so-called interstitial inflammations are really all secondary processes following regressional changes in the liver-cells, this large class of cases can be easily accounted for under the latter heads.

The symptoms presented in children are essentially the same as those seen in adults; ascites, icterus, and pyrexia are often found, and death frequently occurs with symptoms of toxic poisoning, coma, convulsions, etc.

58 East Twenty-fifth Street.

Professor Henoch, of Berlin, the distinguished writer on diseases of children, recently celebrated his seventieth birthday.

REPORT OF A CASE OF OVARIAN TUMOR —ANÆMIA—AND DEATH BY THROMBOSIS OF PULMONARY ARTERY.[1]

By CLEMENT CLEVELAND, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL AND TO THE NEW YORK CANCER HOSPITAL.

Mrs. T—— entered my service, at the Woman's Hospital, November 18, 1889. Her history presented the following points: She was forty-eight years of age, and a widow. Menstruated first at fifteen and was always regular. She was married at twenty-five, and had been a widow for a number of years. She had never been pregnant. Latterly menstruation had been scanty, though of normal duration. Her last menstruation before entering the hospital occurred on November 3d. A little more than a year before she discovered a swelling in the abdomen, below the umbilicus, which had grown steadily ever since. For the past two weeks she has suffered a great deal of pain in the hypogastrium and back.

The measurements of the abdomen give the following: Circumference at largest part, 32 inches; circumference at umbilicus, 31½ inches; ensiform to umbilicus, 7½ inches; ensiform to pubes, 13½ inches; anterior hyoid spine to anterior hyoid spine, 11½ inches. Her general condition bad; profoundly anæmic.

Diagnosis of Abdominal Tumor—Multilocular Ovarian Cyst.—The patient was seen by the late Dr. Hunter during the past spring, and he then diagnosed an ovarian cyst and advised immediate removal. I am informed that the patient was then in good condition and was not at all anæmic. For several months she says she has been unable to take solid food, and that her appetite has been very fitful. She had a horror of a hospital, so she said, and could not make up her mind to enter till her condition became unbearable.

November 28th.—She had a passage containing a large quantity of blood, and a little later passed more blood. After this she fainted, and it was then found necessary to lay her in bed, at which she rebelled and was very unruly on that account. She was put on whiskey, digitalis, and ergot, to no avail. Each day she had the bloody stools. I began to think the tumor must be malignant.

November 30th.—She insisted upon getting out of bed, and at once fainted and fell upon the floor. She vomited often, and was pulseless for some time; but after much difficulty she rallied by the use of hot bottles and brandy, and hot-water enemata.

The patient retained her bed after this, and her condition did not improve.

December 18th.—Patient became pulseless and cold at extremities. There was marked dyspnœa. The patient died suddenly, apparently from œdema of lungs.

The hemorrhages can apparently be explained only upon the blood condition.

Report of Autopsy.—*Head:* Not examined. *Thorax:* Heart normal, muscle pale. Lungs, œdematous; considerable fluid in both pleural cavities. No adhesions. Thrombus of the left pulmonary artery, extending into four of its main branches. *Abdomen:* All the organs are normal but pale in color. *Pelvis:* Right ovary replaced by a large multilocular cyst, which extends upward into the anterior region of the abdominal cavity, reaching from a point about two inches below the stomach to the pubes, and extending from one side to the other in a transverse direction. The omentum is drawn down over the anterior surface of the cyst and firmly attached to its lower third. The cyst is an irregular ovoid mass measuring 61 × 52 ctm. in circumference. Left ovary enlarged, irregular in shape, measuring 6 × 3 × 4 ctm. Two small, thinned-walled cysts are attached to one end of the ovary.

The cyst was hardened in Flemming's chromic acetic acid mixture. The composition of this fluid is as follows: one per cent. aqueous solution of chromic acid, 25

[1] Read before the Practitioners' Society of New York, May 23, 1890

parts; one per cent. aqueous solution of hydric acetate, 10 parts; water, 70 parts.

The fluid contents of the tumor having been removed, the above fluid was injected into its cavity under a pressure of eighteen inches of water, until the cyst was distended to its natural size. The distended cyst was then placed in a large quantity of the above fluid for fifty-six hours. It was then removed, the fluid in its interior drawn off, and the cyst washed in water until the latter ceased to be tinged yellow. It was then placed in eighty per cent. alcohol for further hardening.

The action of the Flemming's fluid is slow and there is but little distortion, the natural shape of the various cysts being well preserved. G. C. FREEBORN, *Pathologist.*

Progress of Medical Science.

Treatment of Long-standing Dislocation of Both Shoulders.—Lister has reported two cases of dislocation of both shoulders remaining unreduced at the end of eight weeks and seven months, respectively. Having ruptured the axillary artery in a case of the same sort, he decided to cut down upon the bone before trying to reduce it. He made an incision from the coracoid process downward and somewhat outward, in the interval between the deltoid and the pectoralis major, and divided the tendon of the subscapularis at its insertion, and then with a periosteum elevator separated the soft parts from the head of the bone and the inner part of its neck. Pulleys were then applied, and as this traction showed some fibrous bands that were put on the stretch, these were divided. As the head of the bone would not return to its position it was protruded through the wound, as for resection, and the external rotators cut through at their insertion. Then, after several attempts with pulley traction, the bone was returned to the glenoid cavity. The wound healed kindly. A week later the other shoulder was operated on in a like manner, except that the head of the bone was immediately protruded and the rotators divided. In seven weeks after the operation the patient was able to dress himself alone, and from that time continually gained power in the arms. In the second case the same operation was done on the left arm seven months after the injury. The right arm was not operated on until six months later. In this case, instead of detaching the soft parts from the bone, the head of the bone was removed with the chisel, when the bone went rapidly into place. After this procedure the return of function did not seem to be as rapid and complete as where the bone was left intact. Both cases after operation were able to earn their living by hard manual labor. As a result of this experience, Lister advises that when the surgeon feels in doubt as to whether it is prudent to make attempts at reduction, or when such attempts do not succeed, he should, in the first place, cut down upon the bone by the usual incision from the coracoid process downward and a little outward, and then, with a curved periosteum-detacher, freely separate the soft parts from the inner side of the upper end of the humerus. If this fails, he may proceed to turn out the head of the bone, detaching the insertions of the rotator muscles. Even if this procedure fail, the removal of the head of the bone is open to us.—*The Annals of Surgery.*

Fracture of the Larynx and Trachea.—A remarkable case of fracture of the larynx has recently been reported by Dr. Desvernine, of Havana. The patient was a man who came under Dr. Desvernine's observation for the first time at the end of 1887. In 1878, being then aged fifteen, he was struck by the cross-bar of a trapeze over the region of the larynx. The immediate symptoms were hemorrhage from the mouth, with intense pain in the throat, dysphonia, and slight dyspnœa. The difficulty of breathing became gradually worse; there was some emphysema of the neck, and tracheotomy had to be performed twelve days after the accident. Except for a certain tendency to catch cold, he remained in good health for several years. When he came under the notice of Dr. Desvernine he was suffering from well-marked pulmonary phthisis. He had dispensed with the tracheotomy tube for three or four years, and breathed through a circular aperture hardly five millimetres in diameter externally. The voice was hoarse but intelligible, deep in tone, and monotonous in *timbre*. On laryngoscopic examination the cords were seen to be completely fused together, forming a uniform plane surface, smooth and red like the rest of the mucous membrane, and presenting a tiny orifice close to the anterior commissure. Posteriorly the arytenoid cartilages were fixed in the adducted position. During phonation the patient closed the tracheal aperture, and the ventricular bands came slowly together in the middle line, so as to form a false glottis, the edges of which were arched upward in the antero-posterior direction, as if by muscular contraction. The infra-glottic region presented no abnormality beyond a diminution in size, owing to thickening of its walls. Dr. Desvernine proposed to divide, *per vias naturales*, the adhesions which bound the cords together; but the operation was declined, and the patient died of phthisis in 1888. On post-mortem examination the line of fracture was seen to have extended from above downward in the middle line, involving the whole of the thyroid and cricoid, and the four upper tracheal cartilages. The ventricular bands were found developed to double their ordinary thickness. This was due to hypertrophy of the muscular fibres in the bands and in the aryteno-epiglottic folds. The condition of the glottis was as above described, the crico-arytenoid articulations being firmly anchylosed, and the dilator, adductor, and tensor muscles much atrophied. Microscopic examination of the vocal cords showed that their amalgamation was the result of acute inflammation. The case is interesting as proving that in some cases the ventricular bands may to a certain extent take on the action of the true cords, and serve for the production of voice. The air came through the small aperture (measuring 2 millimetres in length and $1\frac{1}{4}$ in breadth) at the anterior commissure, and the ventricular bands were distinctly seen to vibrate during phonation; on the patient withdrawing his finger from the aperture in the trachea, movement and sound alike ceased. Dr. Desvernine is inclined to believe that the phthisis was an indirect result of the accident, from the insufficient aëration of the lungs and the proneness to catarrh induced by the condition of the larynx.—*The British Medical Journal.*

Secretion of Blood Instead of Milk.—Dr. Habergritz reports a case of the secretion of blood in the breasts. The patient was a young married woman who, when she had been pregnant with her first child about six months, consulted Dr. Habergritz as to whether the fœtus was alive. He noticed some blood stains on her linen in the neighborhood of the breasts, and on examination found that drops of pure blood could be expressed. The patient said that the bleeding had begun when she was five months pregnant, and she did not know that it was an unusual occurrence, and therefore had not mentioned it. During the rest of the pregnancy the phenomenon continued, and the patient suffered besides from two or three attacks of epistaxis. Two days before labor came on the bleeding ceased, but it reappeared in increased amount the day after. The patient was very anxious to nurse the child, but as it drew nothing but blood this had to be put a stop to. On the seventh day the color of the secretion began to change, and by the eighth it had all the characters of ordinary colostrum. The child was then allowed to take the breast, and nothing further abnormal was observed. It should be mentioned that the woman was perfectly healthy; there were no traces of gout, hæmorrhoids, cancer, or of hemorrhagic diathesis.—*The Lancet.*

The Treatment of Gonorrhœa by Salol.—Dr. Lane says that for some time past he has been prescribing salol in the out-patient department of the London Lock Hospital, and has now tested its value in urethral discharges at all stages, in some cases relying solely on its use, and in others employing an astringent injection in addition. An analysis of fifty cases in which he used this drug shows that six were cured, twenty-four showed considerable improvement, and fifteen no change whatever; while in five cases the symptoms were aggravated (*The Lancet.*) The doses ranged from 5 to 30 grains daily, the beneficial effects when present manifesting themselves in a very short time. When improvement takes place the symptoms show abatement in from two to seven days; in acute cases the painful micturition is alleviated early; in cases of a more chronic nature the discharge is materially lessened in this time. The author employed an injection in ten cases in conjunction with salol, the drug then being given in 5-grain doses. Subsequently Mr. Lane increased the dose to 10, 20, and, in some cases, 30 grains, and relied upon its internal administration without the assistance of injections. Out of forty cases so treated an improvement was noticed in twenty within a week, while six were completely cured. Salol is not a mechanical mixture of carbolic and salicylic acids, but appears to be a compound of the nature of an ethereal salt, since phenol can, with some slight difficulty, be obtained from it on saponification. The potassium salt left after the treatment of salol with caustic potash gives, with hydrochloric acid, an acid which is either salicylic or one of its isomers. Four hours after administration by the mouth of 20 grains of salol, traces of carbolic and distinct evidences of salicylic acids, combined with other elements, were found in the urine. In one case the urine was blackened as in carboluria, the patient at that time taking 30 grains three times a day. The effect of salol is apparently produced by the action of the urine upon the inflamed urethra, since that fluid contains salicylates and sulphocarbolates. It may be given in doses of from 10 to 20 grains three times a day at any stage of the disease, and in chronic cases an astringent injection will materially hasten the cure. The effect does not appear to be enhanced by larger doses than 20 grains. When the amount was increased to 30 grains the urine became blackened, and the symptoms did not show any proportionate improvement. The author commenced his experiments by giving 5-grain doses, and in all probability his tables would have been much more favorable had he administered the drug with a freer hand.

Acute Tubercle of Joints.—Miliary tubercle of the synovial membrane of joints is of fairly common occurrence, but as a solitary affection is very rare. Dr. Chamarro describes this condition as acute tubercular hydrarthrosis. He defines it as an eruption of miliary tubercles, accompanied by a copious serous effusion, in the synovial membrane of a joint hitherto healthy, but in a tubercular subject. This complaint was first described by Laveran, in 1876, but has not been generally recognized. König, however, and some other writers, have described a similar affection in the course of acute pulmonary or general tuberculosis, in which the synovial membrane of one or more joints is attacked, causing considerable serous effusion, and in which after death well-marked miliary tubercles are found in the membrane, but inflammatory tissue changes are absent or only very slight. Dr. Chamarro has collected nine cases of the complaint he describes, and forms his conclusions upon them.

The symptoms and course are generally as follows: The patient is always the subject of tuberculosis, although this may be obscure, being occasionally situated in the urinary tract. A joint, generally the knee (very rarely more than one joint), which has hitherto been healthy, becomes swollen without any apparent cause. The swelling appears very quickly, rising within a few hours, very often in the course of a night. There is generally a considerable amount of pain, especially if the effusion be considerable. The signs of fluid are well marked, and there is often an œdematous condition of the cutaneous coverings. Pressure on the capsule of the joint causes great pain, but none is produced by pressing the articular surfaces together, thus distinguishing it from a tubercular affection of the bones. Absorption of the fluid occurs in from ten to thirty days, and a complete cure may follow; usually, however, a permanent thickening remains, not to be distinguished from "white swelling," or "gelatinous," or "pulpy degeneration." In the cases described by Chamarro, two recovered and two lapsed into a chronic state; the life of one of these patients was saved by amputation through the thigh, the other eventually died. The remaining five patients died, shortly after the acute joint affection set in, of tuberculosis of the lungs or meningitis. In all these five cases at the necropsies there was pronounced miliary tuberculosis of the synovial membrane of the joint affected; but there were no, or very slight, inflammatory changes in the subsynovial tissues, and the cartilages and bones were entirely unaffected. Giant cells were never found. The recognition of this condition Chamarro rightly thinks is of great importance, for such swelling may be diagnosed as gonorrhœal, or due to acute rheumatism; the discovery of a tubercular affection in the lungs or elsewhere would correct this error. The thickening of the capsule occurs early, and must be carefully watched for. The pain is not usually so great as in other joint affections. As regards the treatment, Chamarro recommends rest, leeches to the affected joint, painting with iodine, and blisters. He suggests that the capsule might be punctured and the joint washed out with antiseptic fluid.—*The Lancet.*

Partial Resection of the Liver.—Dr. Vohtz has recorded this case: A woman, aged twenty one, had observed a tumor in the abdomen for some nine years. This had rapidly increased in size after a second confinement, eleven months before. There was found a spherelike, smooth, and tensely fluctuating tumor extending below a line drawn from one iliac spine to another, and above not to be separated from the liver. It was the size of a child's head, easily displaceable to either side or upward, and but little downward. It had no connection with the sexual organs. It was diagnosed as an omental tumor, on account of its great mobility, and laparotomy commenced, when an echinococcus, occupying the lower and posterior surface of the liver, was revealed. It was excised, and with it a part of the greatly atrophied hepatic tissue was removed. The large and not greatly bleeding wound was united by a strong continuous suture, so that a crest-like elevation was the result, and the abdominal wound was closed. Recovery was uneventful, excepting a slight increase of temperature during the first days after the operation.—*Annals of Surgery.*

Pharyngitis Ulcerosa Lateralis.—Dr. Heryng has made a communication on a new pharyngeal disease, which he proposes to term pharyngitis ulcerosa lateralis, or ulcus ovale pharyngis, while some colleagues of his suggest the name ulcus Heryngi. As the author's observations of nine years' duration have established, the affection is characterized by the appearance on the lateral pharyngeal walls of painless, invariably oval, gray ulcers, measuring 1 ctm. in length, and from 0.5 to 0.7 in breadth, and surrounded by a congested zone. They are preceded by fever and malaise, which subside in two days, while the ulcers heal in ten days, without leaving any visible scars. The pathogenesis remains yet obscure. Drs. Heryng and Odo Bujwid. succeeded in isolating from the discharge two species of microbes, one of which proved to be the ordinary streptococcus of erysipelas, the other being a new variety described by Dr. Bujwid as a streptococcus variegatus. The inoculation experiments on animals (rabbits, guinea-pigs, and mice), however, gave negative results.—*The Provincial Medical Journal.*

THE RAPID HEART.

A CLINICAL study of tachycardia has been published by Dr. A. E. Sansom, who chose this title for the recent "Annual Oration of the Medical Society of London." The author aptly remarks at the outset that there are very few members of our profession, whatever their line of practice, who have not been occasionally perplexed concerning cases manifesting disturbances of the normal action of the heart. Such perplexities have probably occurred in regard to diagnosis, prognosis, and treatment. There have been difficulties in determining whether the perturbations witnessed were due to, or were the disposing causes of, organic heart disease. There have been dangers of overestimating and of unduly depreciating the signs of disturbance; so in the one case the anxieties of the patients and their friends may have been rendered needlessly acute, and in the other a delusive optimism may have been rudely checked by the fatal logic of events. And certainly, with reference to questions of the therapeutics of such disorders, it cannot be said that science is yet satisfied.

Dr. Sansom has limited his remarks to that form of disturbance in which the heart's action is morbidly accelerated, or, at any rate, in which such acceleration is the chief feature. The effects of fever, the influence of certain germs, of anæmia or hemorrhage, the operation of poisons, and even those cases which have been described as "paroxysmal hurry of the heart," are not included in his present inquiry.

He considers the average rate of the cardiac cycles in the healthy male as 72, and in the healthy female as 80 per minute, in the recumbent posture, in each case. In the erect position these rates may be raised to 80 and 90, respectively. Seeing that very slight causes may tend to some acceleration, it can scarcely be affirmed that a heart-rate of 90 in the adult is of necessity abnormal. But a rate of cardiac pulsations observed under varying conditions to be over 90 errs on the morbid side, and requires some explanation of its morbid frequency.

Allusion is made to the familiar fact that the cardiac pulsations of the child are readily excited to a high degree of frequency by causes both intrinsic and extrinsic. Rapid action may occur from such causes of peripheral irritation as worms, as well as from the multifarious conditions of indigestion, accompanied by pain. Sudden terror may induce violently perturbed and rapid action of the heart of the child. According to some observers, such terror may be the initiating cause of chorea, a disease in which the cardiac pulsations, sometimes irregular, are generally morbidly over-rapid, though such rapidity is not extreme.

The cases in which, in adult life, a long-persistent, abnormal rapidity of the heart's action have been observed may be grouped under four headings:

1. Graves's disease, or if due credit be given to everybody, "Parry-Graves-Basedow-Stokes's disease." *En passant*, Dr. Sansom suggests for this complex title the slightly less complicated designation of "cardio-vaso-motor disease."
2. The irritable heart of soldiers.
3. Rapid heart in osteo arthritis.
4. Rapid heart without notable morbid association.

Interesting illustrative instances are given of each of these categories. Dr. Sansom then says that it is clearly proved that the condition of "rapid heart" may be manifested in the subjects of organic cardiac disease, but that it may also arise and progress, or continue for considerable periods, in those in whom no form of organic cardiac disease is known to exist. The question occurs, Is the affection one of the myocardium, or of some portion or portions of the nervous system? Dr. Bristowe is of opinion that it has no special connection with cardiac disease, and that dilatation and hypertrophy of the heart, when occurring independently of valvular mischief, are the slowly developed consequences, and not the causes, of the disturbance. Dr. Samuel West, on the other hand, thinks that cases of (paroxysmal) hurry of the heart are due to an organic lesion of the muscular substance, which may be, in some cases, a form of chronic interstitial myocarditis consequent, perhaps, on rheumatic pericarditis or on syphilis, and thus related to fibroid disease of the myocardium.

Dr. Sansom's personal observations extend to seventy-five cases. These he has divided into two categories. First, those in which there was no association whatever with the recognized cardinal signs of the affection termed by him "cardio-vaso-motor disease" (Graves's disease, Basedow's disease, exophthalmic goitre). In this division are 46 cases—30 females and 16 males. Second, those in which there was an association, more or less marked, with the affection mentioned. This division included 29 cases—24 females and five males.

It is unnecessary to attempt any detailed account of these cases, but certain propositions which he places before us may be mentioned. He believes that the conditions in the two sections of cases manifesting abnormal rapidity of the heart's action are closely allied. This seems to be indicated from the points of view of etiology, consequences, and associations. In both divisions there is strong evidence of the initiating influence of psychical or physical overstrain, or of these causes combined; while in both, also, the condition may develop without such initiating influence. In the one and in the other organic disease of the heart may be manifested, though exceptionally. There seems to be no good evidence to suggest the probability that such structural disease, whether inflammatory or degenerative, is protopathic, or even initiated at a comparatively early period of the malady. On the other hand, there is much to show that it is

secondary to the nervous implication. It is clear that the impairment of the myocardium occasioning dilatation of the cavities may be temporary only in some cases.

He does not think that we should look upon the cases of rapid heart as *formes frustes* of Graves's disease; rather cases of the latter may be regarded as *formes étenaues* of the former. He should interpret the differences between one and the other as differences of extent as regards nervous implication rather than as differences of intensity. In certain cases where the heart rapidity is the only sign of circulatory disturbance the danger to life is extreme.

The signs of more extensive involvement of the nervous system are (*a*) in disturbance of the vaso motor conditions of the great arteries of the neck, whereby these manifest obvious, and perhaps painful, throbbings; (*b*) in like disturbance in the thyroid arteries, which may present dilatations and bulgings; (*c*) in similar affection of the post-orbital arteries, with perhaps such alteration in nutrition as to lead to the accumulation of superabundance of fat. It is to be noted that in the first group, in which the cardio-motor conditions were disturbed without local vaso-motor involvements, murmurs heard over the great vessels emerging from the heart were proportionately far less frequent than in the second section. It seems probable that these murmurs indicated a disturbed correlation between the heart and the arteries. The condition of marked irregularity noticed in some of the cases seems to point to a further nerve involvement. He has evidence to show that an irregularity resembling that present in some cases of Graves's disease may occur without abnormal rapidity, and without any other signs of the cardio-vaso-motor affection. Concurrently with any of the signs mentioned, or with all, there may be an implication of the motor area leading to muscular tremors, and in some cases there may be an impairment of the powers of the mind.

In his present article Dr. Sansom says nothing about the treatment of these disturbances. He only states in a general way that the mild cases were amenable to the influence of ordinary drugs, while the more severe ones proved quite rebellious. Galvanism applied to the nerves of the neck appeared to be beneficial in numerous instances. While it cannot be said that the problems suggested have been solved by the author, his study will be read with interest by all physicians who have to treat true or imaginary cardiac disease.

KRAUROSIS VULVÆ.

In 1885 Breisky brought to the attention of the profession a condition of the female pudenda, which, although not infrequent in its occurrence, seemed so far to have escaped description.

His communication related to eighteen cases which had come to his notice, four of which were described in full, and the remaining fourteen simply enumerated, with the remark that they resembled the others closely. The condition as described by him was one of atrophy of the integument of the external genitals. It was characterized by the presence of more or less extensive patches of shrunken, tense, pearly-white skin or mucous membrane, occupying the upper or lower part of the vulva, the vestibule, or the lower part of the vagina. These patches were sometimes covered with a tenacious secretion, and very sensitive to the touch. When the upper part of the vulva was affected, the skin of the adjacent parts of the mons veneris was dry, pale gray, shining, and provided with few sebaceous glands. The labia minora were very faintly marked and easily effaced by separation of the parts. The prepuce of the clitoris was atrophied and tense, the vagina was narrowed. The mucous membrane of these parts was white, tense, and easily torn. Various disorders were present in different cases, as leucorrhœa, menorrhagia, and pruritus vulvæ.

In 1888 Janovsky published an account of six cases in which a condition of the parts very similar to that already described was present. In these cases certain portions of the altered integument were not thinned like the rest, but opaque and much thickened, appearing like islets in the atrophied surface. Of these six patients two had syphilis and four gonorrhœa.

In 1875 Dr. Weir reported, under the title of "Ichthyosis of the Vulva," a case in which a patch of a pearly-blue color extended from the fourchette over each labium minus. The tissues were thickened, very sensitive to the touch, and covered by a tenacious secretion. Later, epithelioma of the vulva appeared.

In the *New Orleans Medical and Surgical Journal*, March, 1890, Dr. Ohmann-Dumesnil presents a careful review of these cases, and gives an account of ten other cases as yet unpublished, three of which were seen by himself, and the others by his correspondents. In four of these, related by Dr. Heitzmann, parchment-like or horny patches were observed upon different parts of the pudenda, but their color was not noticed, and apparently no extensive atrophy of the adjacent parts was present. In the others, including those seen by Dr. Ohmann-Dumesnil, marked atrophy of the integument was present, and in one or two cases islets of thickened tissue were observed. Pruritus was frequently noted.

The cause of Kraurosis vulvæ still remains unknown. Although in several of the cases irritating conditions were observed, as leucorrhœa, ulceration, irritation from scratching, etc., yet in most of them no such possible cause was apparent. A few of the patients had syphilis, but the disorder did not seem directly due to this disease.

Analogy with certain forms of atrophy of the skin occurring in other parts of the body would suggest that the disorder began as a hypertrophy of the mucous membrane, with mild inflammation and œdema, as in the cases observed by Heitzmann, and that the atrophy, with thinning and tension and effacement of the mucous folds of the labia and clitoris, was a later stage of the same process.

The results of treatment would seem to agree with this supposition, for while the cases of Heitzmann were greatly benefited by treatment, those in which atrophy was clearly marked were not benefited by treatment, or were evidently so far advanced that no treatment was instituted.

Again, if this supposition be correct, the physician ought to be on his guard, and to adopt vigorous measures while the disorder is still in its early hypertrophic stages, seeking by means of repeated curetting, or by the application of lotions of salicylic acid, pyrogallic acid, acetic acid, or Monsel's solution, to destroy the hypertrophied tissues.

THE ECLECTICS.

THE establishment of an Eclectic State Board of Medical Examiners lends some renewed interest to the question, which is often asked, as to what is medical eclecticism. A body of men who assert that they are not simply physicians, but eclectic physicians, must be supposed to use the term in some special and technical sense; for regular or rational medicine is essentially and necessarily eclectic in that it seeks by all legitimate methods to find out the nature, the causes, and the remedies of disease. Eclectic medicine does not, or has not, as everyone knows, stood for any such broad and catholic principles.

There were in 1888 nine eclectic colleges in this country, with 743 students and 220 graduates. In the regular schools there were at the same time 11,172 students and 3,145 graduates. The great majority of the schools and students of eclecticism (538 out of 743), were in the Western States—Illinois, Iowa, and Ohio. In New York there is but one school, which graduated, in 1888, 11 students as against over five hundred graduated by the regular schools. At a low estimate, therefore, the number of eclectic graduates in this State cannot be much more than one fiftieth of the number of regular physicians. And it would be safe to estimate the number of eclectic physicians in New York State at not over one hundred, while there are considerably over three thousand regular physicians. Yet this small band of eclectics is given a State Board and power to license men and women as physicians.

So much for the numerical status of eclecticism. We may now ask: What does "eclectic" medicine, in its technical sense, mean? Fortunately this question has been recently answered by an eclectic himself, the late Dr. Lemon T. Beam, in an earnest address which is published in the *Medical Tribune*, an eclectic medical journal.

The term eclecticism means something besides "choosing the best;" it has, says Dr. Beam, a peculiar significance. "Choosing the best" is to be done "by a certain rule deduced from a radical and distinctive principle," which makes eclectic practice distinctive.

"Disease," says Dr. Beam, "we hold to be impaired vitality and consequent derangement of function. We deduce the *rule* that in disease the body does not require depression or depletion, but rather enforcement or re-enforcement, and this of such nature and quantity as will be sufficient to permit nature herself to carry forward the work of recovery. Added to this is a disposition to investigate, prove, and select that which best serves our purposes."

Eclecticism, according to this, is a system of medical practice based upon the principle of choosing the best remedies in accordance with the theory that disease is impaired vitality.

This sounds well enough, but upon a little examination it will quickly appear that it is blatant nonsense. Syphilis may be a disease in which the vitality is impaired, but if syphilis were treated purely upon this theory the results would be sad enough. The same may be said of many, if not most, other diseases. If eclecticism is based upon this "radical and distinctive principle," as Dr. Beam calls it, the system deserves not even contemptuous notice.

Dr. Beam, however, soon branches off into the "essentials and ethics" of eclecticism, and here he shows what, as a matter of fact, eclectic practitioners do more or less represent.

This consists in a spirit of opposition to all modes of regulating medical practice, and to all submission to special codes of medical ethics. Eclecticism would give every man a chance to doctor his fellow-man, and would give the fellow-man a chance to consult every possible kind of a doctor, from mind-curer to itinerant quack. Dr. Beam is especially severe against the American Code of Medical Ethics, and against all cliques, trusts, prejudice, tyranny, trades-unions, etc. In the sentiments which he expresses, with great fervor and undoubted honesty of feeling, there breathes throughout a spirit of intense antagonism to everything in the nature of code or regulation.

Admitting all the tremendous abuses and dangers about which Dr. Beam writes, it is evident that antagonism to them is hardly the principle on which a school of medicine is to be founded. If eclecticism embodies this spirit it is a school of medical politics, not of the practice of medicine. And we suspect that modern eclecticism represents only a set of men who have peculiar opinions about medical polity.

The question as to the value and truth of their opinions is one which involves a discussion of the whole subject of higher medical education, and its supervision, more or less, by the State. The conclusions of the vast body of disinterested and intelligent men who have studied the matter are on the side of some such State supervision as will help to prevent the people from becoming the victims of ignorance and quackery.

There is no place for a special school of eclecticism such as we have described, and such as its own members claim it to be. It will gradually die out, as it is, we believe, already doing. Meanwhile its influence is not especially bad, and numerically it is too weak to block seriously the progress of sounder education and more rational medicine.

A NEW BLOOD-CELL.

THE blood is the Central Africa of pathological anatomists and physiologists. Every now and then some new explorer dives figuratively into its mysterious depths and returns with some new corpuscle, or granule or parasite. The trophies brought back by these adventurers often match very well the hopeless barrenness of an equatorial possession. We recall the ridiculous yeast-spores of Salisbury, the new colorless cells of Norris, the crystals, granules, crenated cells, and hypothetical micro-organisms of other ambitious and enthusiastic discoverers.

Despite many mistakes and misadventures, however, our knowledge of the physiology and pathology of the blood is steadily advancing, and we have read with much interest a recent original contribution to the subject by Dr. Alexander Edington, of Edinburgh. This gentleman, who is a surgeon and a bacteriologist, has been studying the morphology of the blood by the help of certain stains. The methods employed were to seal a drop of fresh blood under a cover (adding sometimes a drop of staining fluid), and the ordinary dried-film method. The stains used

were the aniline dyes, especially dahlia. By means of these methods Dr. Edington was able to make out the shape and number of the nuclei of the white blood-cells, the changes in the cells in different stages of development, and certain peculiarities in their structure. He also believes that he has discovered a new corpuscle. He has introduced a number of new terms to designate the forms which he describes.

The following represent the results of Dr. Edington's discoveries and views: He finds that the white blood-corpuscles contain, in their simpler and earlier stages of development one, or, at most, two nuclei. After a time four nuclei appear. These nuclei at last discharge themselves and form free nuclei or daughter nuclei. Some of these develop into white blood-corpuscles again, while others go to form a multi-nucleated cell, also of the nature of a white blood-cell, but having peculiar functions. This cell is called a matricyte. The matricyte swells up, discharges its many nuclei, which now form what is called an "albocyte." The "albocyte" is Dr. Edington's new blood-cell. It is a small, spherical, colorless cell having about one-third the diameter of the red cell, *i.e.*, 1 μ. to 4 μ. These cells gradually enlarge, take up hæmoglobin, and assume the biconcave shape of the fully developed red blood-cell. The latter cell is believed to have a very thin enclosing membrane. The albocyte is not identical with the hæmatoblasts of Hayem. These latter structures are composed of granular material originating from the white blood-cell, and they, together with the white cell, are concerned, as Hayem states, in the formation of fibrin.

We have now, according to Edington, in the blood, 1, the white blood-cell and its daughter nuclei; 2, the matricyte; 3, the albocyte; 4, the red blood-cell; and, 5, the granular bodies known as hæmatoblasts.

Dr. Edington's observations are illustrated by a large number of careful drawings and by a full description of his *technique*. He is, we believe, one of the first to make an elaborate study of the blood with the help of modern staining methods, and his researches demand attention from their novelty and the importance of his conclusions.
ment, receives a disproportionate amount of attention, since no less than five chapters, or one hundred pages, are devoted to it. This subject (the consideration of which is unquestionably proper and necessary in its place) is a favorite one with our French *confrères*, who in their public lectures and writings handle it with a freedom and attention to prurient details which would be regarded as little short of indecent by an English-speaking audience. For example, the interesting conversation reported on pages 408 and 409 seems strangely out of place in a surgical monograph. We believe in "giving the imagination some chance." Artificial impregnation is the delicate theme which concludes the volume; it is hardly necessary to add that it is "handled without gloves."

To summarize, this manual contains much that is useful and interesting, but a good deal of matter that only acts as so much padding to a form that is already sufficiently rotund. The omission of at least two things of the subject-matter, and the condensation of the remainder, would [illegible] the book a really practical one.. [illegible]garten," at the recent meeting of the British Medical Association, is said to have been highly appreciated by the two thousand guests who were in attendance.

Surgeon-General Gordon states that tropical Africa cannot be colonized by the English race.

The Third International Shorthand Congress took place this year, from August 7th to 17th, at Munich, and the centenary of the birth of F. X. Gabelsberger, the founder of German shorthand, was celebrated in conjunction with it. A gigantic bronze statue was unveiled in honor of the inventor.

The Swiss in Favor of Intubation.—The *Correspondenzblatt für Schweizer Aerzte*, of August 1, 1890, says that reliable figures show that this operation is not to be discarded for merely theoretical reasonings. This is a hint for Germany, where the method in question has but few friends, owing doubtless to its American origin.

Proposed New Leper Asylum for Calcutta.—As the existing asylum is inconveniently situated, the Bengal Government has appointed a committee to consider the question of a new leper asylum for Calcutta. According to the last census there were 387 lepers in Calcutta, but it is supposed the number is now much larger.

The Admission of Female Students to the Johns Hopkins University.—American women have taken advantage of the poverty of the Johns Hopkins Hospital to make a bargain with the authorities which should be to the benefit of all. The somewhat straitened financial condition of that institution suggested the possibility of contributing to its relief, and at the same time hastening the establishment of a medical school in which the benefits of the highest medical training shall be afforded to women. To this end they propose to raise the sum of $200,000, which is to be given to the trustees on the distinct condition that women, whose previous training has been equivalent to that of an ordinary preliminary medical course, shall be admitted to the institution on precisely the same terms as men. Committees are at work in six of the principal cities, including Boston and San Francisco, and considerable contributions have already been made to the furtherance of the movement.—*The Hospital.*

Physiology of Electrical Currents.—Recent experiments on the physiological effects of the electric current lead to the belief that a continuous current causes death by a direct action on the substance of the heart, and death by an intermittent current is due to the alteration of the nerves and the inhibitory mechanism of the heart

Another School of Medicine for England.—It is reported that the Court of Governors of the University College of South Wales and Monmouthshire have recently adopted a proposal to establish a department of medical science in connection with the institution under their charge.

A Proof in Black and White.—When a woman conceives and has twins, one being white and the other a negro, it is evident that the fact of superfœtation has been proved in black and white.

Something to be Proud of.—It seems that Dr. John M. Crawford, Consul-general of the United States at St. Petersburg, has made a great hit with the royal household. The Czarina, who had heard of his translation of the epic poem of Finland, "The Kalevala," invited him to the palace. She actually had some conversation with him. To cap the climax, she graciously requested him to present her with a copy of the translated epic. Thus doth royalty bestow inexpensive favors on the sons of a great republic.

The American Rhinological Association will meet at Louisville, Ky., October 6, 7, 8, 1890.

The Newly Appointed Leprosy Commission is to consist of three persons, a nominee of the Royal College of Surgeons, one of the Royal College of Physicians, and a member of the present Leprosy Committee.

Dr. Lomax, a venerable physician of Indiana, has given real estate worth from $75,000 to $100,000 to the Indiana Medical College at Indianapolis.

It is Reported that Mrs. Ayer, whose husband made some money in the patent medicine business, proposes to erect a three million dollar hospital for consumptives in New York.

Mississippi Valley Medical Association.—The seventeenth annual session of the Mississippi Valley Medical Association will be held at Louisville, Ky., Oct. 3–10, 1890. Gentlemen wishing to read papers will send titles to the Secretary, Dr. E. S. McKee, 57 W. Seventh Street, Cincinnati.

Death of Dr. J. A. Allen.—Dr. J. Adams Allen, Dean of Rush Medical College, Chicago, is dead. He was sixty-five years of age.

Pyoktanin is said to be useless by Dr. Kölliker, of Strassburg. Dr. Braunschweig calls attention to the disagreeable symptoms of irritation which are produced, and to the small degree of success he obtained with it. Dr. Barclay, on the other hand (as will be seen by referring to p. 221 of this issue), records several cases of its successful use.

Famine Fever, which means typhus fever following in the wake of famine, has appeared in Ireland. The crops are ruined.

The Ontario Medical Society. — The tenth annual meeting of this association was held at Toronto, Dr. J. A. Temple, of Toronto, president. About two hundred and fifty members were present. The president's address contained a strong plea for a uniform license in the Dominion.

A University for Nantes is contemplated, to supply the needs of Western France.

An Unpleasant Predicament.—A Paris correspondent states that the Montpellier municipality has resigned on account of the Government having half-promised a medical faculty to Marseilles. The result is that marriages are at a standstill, there being no mayor to officiate.

Plutocracy and Small Families.—It is reported that a recent census of Fifth Avenue has established the fact that the average number of children to each family is a fraction of—one. We doubt the accuracy of this statement. But it is quite true that the rich, as a rule, beget much smaller families than the poor. Misery loves company. Wealth is circumspect, and knows how to thwart nature.

Is the British Medical Association in Decadence?—The *Hospital Gazette* says that, in connection with the late meeting at Birmingham, one circumstance has been the subject of much comment, and that is the almost entire absence of the "leaders of the profession." Time was when the chief hospital physicians and surgeons of London, Edinburgh, and Dublin attended the meetings of the Association, but of late years they have attended in fewer numbers, and this year they appear to have "boycotted" the meeting altogether. Since last year sixty-seven metropolitan members, mostly consulting physicians and surgeons, resigned in a body on account of their dissatisfaction with the editing of the *Journal*, and this appears to have shaken the Association more than might have been expected. A few more such blows and the Association would crumble to pieces.

An Incorrect Secretary.—Dr. Lassar, the Secretary of the International Medical Congress, is said to have left Berlin for New York to escape the consequences of his rudeness while conducting the Empress through the exhibition. Besides this, his official statements at the last meeting of the Congress now prove to be incorrect. The delinquent doctor's friends excuse him on the ground that his nerves are overstrung, and that, therefore, he is not responsible for his actions.

Cholera Extending.—The latest information about cholera is to the effect that it has continued to advance. Some cases are said to have appeared at Cairo. It has also been carried to London. It continues its ravages in Spain, Russia, and along the shores of the Red Sea. *The Times* says that the English might improve the sanitary condition of India, and it is their duty to do more than they have done, or have sought to do, there. It should not be expected, however, that sanitary progress will be perceptible in the "home of cholera," except so far as the army and the foreign residents are concerned. But if in India the almost incredible pollution of streams and reservoirs and tanks, and the other pestilential practices of the wretched inhabitants cannot be prevented, it is possible for the nations of Europe to unite in guarding the paths that lead from India to the Mediterranean. It is possible for them to exercise a police power over the ports on the Persian Gulf and the Red Sea, and over the traffic in those waters. It is possible for them to establish and maintain throughout the approaches to the Mediterranean a quarantine or a system of sanitary inspection that would afford protection. The cost of such a system

A NEW BLOOD-CELL.

THE blood is the Central Africa of pathological anatomists and physiologists. Every now and then some new explorer dives figuratively into its mysterious depths and returns with some new corpuscle, or granule or parasite. The trophies brought back by these adventurers often match very well the hopeless barrenness of an equatorial possession. We recall the ridiculous yeast-spores of Salisbury, the new colorless cells of Norris, the crystals, granules, crenated cells, and hypothetical micro-organisms of other ambitious and enthusiastic discoverers.

Despite many mistakes and misadventures, however, our knowledge of the physiology and pathology of the blood is steadily advancing, and we have read with much interest a recent original contribution to the subject by

surgeons. The treatment of cysts on the upper surface of the liver, and of all deeply placed and obscure cysts, is yet unsettled, and requires further experience; but so far laparotomy, if only for exploratory purposes, seems advisable. This is about the way hydatids are treated outside of Australia."

Reviews and Notices of Books.

Leçons de Gynécologie Opératoire. Par Vulliet, Professeur à la Faculté de Médecine de Genève, Ex-Chirurgien de la Maternité, etc., et Lutaud, Professeur libre de Gynécologie à l'Ecole pratique, Médecin adjoint de Saint-Lazare, etc. Deuxième édition entièrement refondue. Avec 200 Figures intercalées dans le Texte. Pp. 500. Paris: A. Maloine, Libraire-Éditeur, 91 Boulevard Saint-Germain. 1890.

These lectures are preceded by a short introductory chapter, which, with the two following ones on pelvic examination, might have been omitted without detracting from the value of the work. This criticism applies to all of the manuals on operative gynecology now extant, in which there is an unnecessary amount of detail with regard to pelvic anatomy and the ordinary methods of examination, with which it may be assumed that every advanced student should be familiar before he essays to master the details of gynecological operations. With true French prolixity the authors devote an entire lecture to the sound, entering into details which only tend to confuse the beginner. Vulliet's method of dilatation is clearly described and illustrated. The fifth chapter is devoted to the subject of artificial prolapse of the uterus, the sixth to curetting. With the latter we really begin the subject of surgical gynecology, the first hundred pages being purely introductory. We approach the chapter on Emmet's operation with no little curiosity, since foreign writers usually make a lamentable failure in their efforts to describe its details. The present description is no exception to the rule. The "uterine tourniquet" is ancient history. None of the present generation of gynecologists has even seen or heard of it, and its inventor rarely used it. Hemorrhage during operations on the cervix is a bugbear which vanished long since. Two lessons are devoted to the palliative and surgical treatment of fibroid polypi. The eleventh includes a valuable *résumé* of the principles and practice of pelvic massage. The twelfth to the fourteenth (inclusive) treat of cancer of the uterus, including the details of vaginal hysterectomy. The two following lectures are a little out of place in a surgical manual, since they deal with displacements and pessaries. The eighteenth is one of the most interesting, as it contains descriptions of the Alexander-Adams operation and hysterorrhaphy; the twentieth is the longest of all (fifty pages), and deals thoroughly with the subject of colpo-perineorrhaphy. Sterility, its causes and treatment, receives a disproportionate amount of attention, since no less than five chapters, or one hundred pages, are devoted to it. This subject (the consideration of which is unquestionably proper and necessary in its place) is a favorite one with our French *confrères*, who in their public lectures and writings handle it with a freedom and attention to prurient details which would be regarded as little short of indecent by an English-speaking audience. For example, the interesting conversation reported on pages 408 and 409 seems strangely out of place in a surgical monograph. We believe in "giving the imagination some chance." Artificial impregnation is the delicate theme which concludes the volume; it is hardly necessary to add that it is "handled without gloves."

To summarize, this manual contains much that is useful and interesting, but a good deal of matter that only acts as so much padding to a form that is already sufficiently rotund. The omission of at least two things of the subject-matter, and the condensation of the remainder, would render the book a really practical one; but in its present form it can only be of value to French students, who are probably accustomed to reading a page in order to acquire information which might have been condensed into a single sentence. On the other hand, many of the descriptions of operations are fresh and graphic, and not a few of the illustrations are excellent. The absence of an index is to be deplored.

The Suppression of Consumption. By G. W. Hambleton, M.D. New York: N. D. C. Hodges.

This is one of a series of monographs on scientific matters of general interest, entitled "Fact and Theory Papers." The author takes the ground that consumption is the "direct result of the reduction of the breathing surface of the lungs below a certain point in proportion to the remainder of the body, and is solely produced by conditions that tend to reduce the breathing capacity." For treatment he advocates out-door living and exercises to develop the chest.

Essentials of Examination of Urine. By Lawrence Wolff, M.D. Saunders's Question Compends.

A good manual for students to begin with, but too meagre for any other purpose. Contains nothing essentially new, but is well written, and answers categorically many of the questions beginners are sure to ask.

Essentials of Diseases of the Skin. By Henry W. Stelwagon, M.D. Saunders's Question Compends.

The writer's wide experience in furnishing articles on Dermatology for other works prepares us to expect success in his present attempt to bring the leading facts of this branch of medicine down into the form of questions and answers. We are not disappointed. An immense amount of literature has been gone over and judiciously condensed by the writer's skill and experience. Where the work of preparing students' manuals is to end we cannot say, but the Saunders series, in our opinion, bears off the palm at present.

The Clinical Use of Prisms and the Decentring of Lenses. By Ernest E. Maddox, M.D. Pp. 113. London: Hamilton, Adams & Co. 1889.

As is implied in the title, this book covers the ground of the mathematics of lenses and their practical application to clinical cases. Their geometrical and optical properties are first considered; then follow sections on marking the apex, prismetry, planeness of surface, and directions for trials of prisms. Succeeding chapters treat of decentring of lenses, localization, analysis of spectacles, etc. It is a carefully written technical book, of interest to ophthalmologists only.

Diabetes Mellitus and Insipidus. By Andrew H. Smith, M.D. New York.

These pages of very readable facts form one of the monographs published by George S. Davis, of Detroit (1889). Especial attention is paid to the topics of prevention and treatment, and discussion concerning pathology is purposely avoided. The principal interest in a work of this kind, written by such a well-known practitioner as Dr. Smith, centres around the recitals of his own experience, and this, again, chiefly with reference to matters medicinal, for all authors practically agree on hygienic and dietetic points. The writer highly extols saccharin as a dietetic substitute for sugar. He believes that morphine will unquestionably diminish both the polyuria and glycosuria, but it should be given only in the first stage, and again in the very late stage when the system is overtaxed by the sugar formation and it becomes justifiable to incur a less danger to avert a greater. He has not used antipyrin, but regards the clinical evidence in its favor as very strong. Clemens's solution has worked well. The whole chapter on treatment is a well-arranged digest of accumulated knowledge.

Les Insectes vésicants. Par Professeur H. Beauregard. Avec 34 Planches et 44 Figures dans le Texte. Paris: Félix Alcan, Éditeur. 1890.

This is a large volume, giving a complete history of the vesicating insects, their anatomy, physiology, pharmacology, zoölogy, development, and classification. It is a work indispensable to students of materia medica and pharmacology, as well as of natural history.

CONTRIBUTION À L'ÉTUDE DE LA SYRINGOMYÉLIE. Par le DOCTEUR T. BRUHL. 1 vol. 8vo, 221 pages, with 12 Illustrations. Paris: Progrès Médical.

SYRINGOMYÉLIE is a very rare affection, but one which has attracted much attention of late. Good monographs have appeared on the subject in Germany and in France. Roth has made a valuable contribution to the subject. Bruhl brings the subject down to date, and adds some hitherto unreported cases.

ESSAI CRITIQUE SUR L'INTOXICATION CHRONIQUE PAR LA MORPHINE ET SUR SES DIVERSES FORMES. Par le DOCTEUR REGNIER. 1 vol. 8vo, 169 pages. Paris: Progrès Médical.

DR. REGNIER has already published some useful and scholarly monographs, and the present one adds measurably to his reputation as a careful writer and experienced physician. He dwells especially upon the importance of preventing the morphine habit by the regulation of the sale of the drug, and by care on the part of physicians. The monograph contains a large amount of interesting clinical matter.

STRICTURE OF THE MALE URETHRA: ITS RADICAL CURE. By FESSENDEN N. OTIS, M.D., New York, late Clinical Professor Genito-urinary Diseases in the New York College of Physicians and Surgeons. 8vo. Pp. 352. New York: G. P. Putnam's Sons.

INASMUCH as the book bears the imprint 1878 we are not led to look for anything new. Dr. Otis's views have been too long before the public to need any recital here. The volume is somewhat interesting historically, as it gives, in full, the various papers read at different times by the author before different societies, and, as well, the ensuing discussions by our leading surgeons, some of whom are already dead. The historian of dilating urethrotomy will have to rely much on the information here given.

DISEASES OF WOMEN. By CHARLES H. MAY, M.D. Second edition, revised by LEONARD S. RAU, M.D., Attending Gynecologist to Harlem Hospital, etc. Pp. 373. Philadelphia: Lea Brothers & Co. 1890.

THE first edition was published five years ago as a concise manual for students and practitioners. No originality was claimed. It purported to be a *résumé* of current teaching of our leading gynecologists, with a local tinge from the instruction given in this branch at the New York College of Physicians and Surgeons. In this second edition the chapters on "Methods of Examination" and "Affections of the Fallopian Tubes" have been practically rewritten. New illustrations appear throughout, and a wider range of literature has been consulted. The criticism of a book of this kind is simply concerning its style and arrangement. These, in the present instance, we unhesitatingly commend. Condensation seems to have been carried to the farthest point practicable, and yet vagueness of meaning and incompleteness of statement have been avoided.

CHEMISTRY, ORGANIC AND INORGANIC. By CHARLES LOUDON BLOXAM. Seventh edition, revised and enlarged by JOHN MILLAR THOMPSON, Professor of Chemistry, King's College, and ARTHUR G. BLOXAM, Demonstrator of Chemistry, Royal Agricultural College, Cirencester. 8vo. Pp. 799. Philadelphia: P. Blakiston, Son & Co. 1890.

THIS edition brings the subject-matter up to date. Concise accounts of modern research are given in the organic division, such as Raoult's method for the determination of molecular formulæ, and Fischer and Tafel's investigations in the synthesis of sugars. Our present knowledge on the chemistry of vegetation is fully set forth. The portions relating to explosives have been carefully revised. The general arrangement of the subject-matter is the same as in former editions. A copious index is a valuable feature.

THE PULSE. By W. H. BROADBENT, M.D. Illustrated with 50 Sphygmographic Tracings. Pp. 307. Philadelphia: Lea Brothers & Co.

DR. BROADBENT'S little work covers a subject for which too much familiarity has bred a certain degree of indifference. We regard his book, therefore, as being a most useful one, for it gives in a simple and direct manner the methods of examining the pulse and its characteristics in various diseases. Dr. Broadbent says but little about the sphygmograph, and thinks it an instrument whose use requires much experience.

DIE ZUCKERHARNRUHR. IHRE URSACHE UND DAUERNDE HEILUNG. Von MED. DR. EMIL SCHNEE. Stuttgart Süddeutsches Verlags-Institut. 1888.

IN this short monograph on diabetes there is collected a good deal of information regarding the disease, but nothing new is given us either as regards pathology or treatment.

DE L'ACROMÉGALIE. MALADIE DE P. MARIE. Par SOUZA-LEITE. J. D. Avec 102 Figures dans le Texte. Paris: Lecrosnier et Babé, Libraires-Éditeurs. 1890.

THIS is a large book on an extremely curious and rare disease. It consists chiefly of a compilation of the previous writings of Marie describing his cases. The author adopts the French custom of naming the disease after its early describer. The practice is begotten of vanity, and is unscientific and cumbersome. With all respect to M. Marie, we hope that acromegaly will not be known as "Marie's Disease."

STORIES OF A COUNTRY DOCTOR. By WILLIS P. KING, M.D. With Illustrations by T. A. Fitzgerald. Pp. 397. Kansas City, Mo.: Hudson Kimberly Publishing Company. 1890.

DR. KING'S book deals with the experiences of a country practitioner in the West. The first chapters describe many interesting phases of pioneer life. The latter part is a story of the odd and interesting in the everyday life of a general practitioner. Dr. King has made a really valuable contribution to the knowledge of the social life of the West as it was some years ago. His observations show him to be a man of sound sense and good feeling, as well as of thorough knowledge of the weak and the strong points of frail humanity.

Those who expect extremely funny stories will be rather disappointed. The author may have a keen sense of humor, but he hardly has the power of putting it into literature. His book is well written, however, and has the merit of being easy and interesting reading. Physicians will enjoy it because it will recall pleasantly their own ups and downs. The laity can read it with profit, too, for it will show them humanity from the doctor's stand-point, and no one has a position of better vantage than he.

THE MICROTOMIST'S VADE-MECUM: A Handbook of the Methods of Microscopic Anatomy. By ARTHUR BOLLES LEE. Second edition. 8vo, pp. 413. Philadelphia: P. Blakiston & Co. 1890.

THE "Microtomist's Vade-mecum" is announced as a second edition of a work published in 1885. It is in fact, however, so much enlarged and changed as to be practically new. The author aims to furnish, not so much a text-book for the beginner, as a manual for the working microtomist (as Mr. Lee chooses to call him). The book contains a concise account of all the known methods of preparing specimens for microscopical study. He has purposely omitted bacteriological technique, but, on the other hand, his work is adapted not only for the human anatomist, but for students of zoölogy in general.

An examination of Mr. Lee's book convinces us that it is most complete in every way, and cannot fail to be a help to those who are desirous of keeping abreast of the times in matters of microscopical technique.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 2, 1890.

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

Progressive Muscular Atrophy.—DR. C. L. DANA presented a man, forty years of age, with Erb's type of juvenile muscular atrophy, or, as the disease was called at present, progressive muscular distrophy. The patient said that his great-uncle and father had a similar disease. In his father it began in the same way as in himself, at the age of twenty, and lasted till death, which took place at the age of forty-three. The other members of the family were healthy. The patient's disease began, without any known cause, at the age of seventeen, manifesting itself first by weakness and atrophy in the left shoulder. Then the other shoulder, then the left thigh, then the right thigh became involved, and of late years the forearms, and to some extent the legs, had become affected. The muscles of the back had not entirely escaped. The face, tongue, and all parts above the shoulder were not involved. The general health had been good, and there had been no other symptoms than the muscular atrophy. He had been able to go about his business as a carpenter until within a year or two. The symptoms were purely those of muscular atrophy, the paresis being due solely to such atrophy. There was no anæsthesia, no pain, no trouble with the bladder or rectum; the appetite was fairly good.

Dr. Dana said there were two grand groups of progressive muscular atrophy, the one of spinal, the other of muscular, origin. The atrophy beginning in the muscles was of a hereditary type, affecting families. Clinicians had made a large number of subdivisions, depending upon the group of muscles most affected. In some it began in the shoulders, constituting what had been recognized as Erb's juvenile muscular atrophy; in others it began in the face (the Landouzy-Degerine type), and still others in the lower extremities. Pseudo-muscular hypertrophy was simply another type of the same affection. The disease generally began in early life, progressed slowly; the atrophy was not associated with fibrillary twitchings, there was no reaction of degeneration as there was in muscular atrophy of spinal origin.

In the patient presented there seemed to be some pseudo-hypertrophy associated with the atrophy, manifest in the calves of the legs. The pectoral muscles seemed somewhat atrophied, but the patient was able to greatly expand the chest, showing that the intercostal muscles had not been affected. Usually the female line was affected in this disease. The patient was able to trace his ancestry back some distance, through an American history, to the English, and Dr. Dana believed that usually it was the degenerative types that were seen in Americans, while functional neuritis was more commonly imported. Replying to a question by Dr. Partridge, he said that under the microscope one found in progressive muscular distrophy wasting of the muscle and deposition of fat. Erb stated that there was sometimes enlargement of individual muscular fibres.

DR. H. M. BIGGS mentioned the case of a man, aged twenty-four years, whom he saw in the hospital last year with the pseudo-hypertrophic type of muscular atrophy. The calves and thighs were enormously enlarged, as were all the muscles, yet the man was scarcely able to ascend a pair of stairs. The disease in this case was hereditary. He had seen five or six cases of the pseudo-hypertrophic type in children.

THE PRESIDENT inquired of Dr. Dana whether it was not true that we saw the pseudo-hypertrophic type more frequently in children because the disease was hereditary, and as time elapsed it passed into the atrophic form.

DR. DANA said he thought the pseudo-hypertrophic form was pretty distinct clinically, was more common than the other, almost always began in the legs, and ran a pretty regular course.

THE PRESIDENT said that some years ago he saw a good many cases of the pseudo-hypertrophic form in children at Dr. Seguin's clinic, and he recalled that in one family three children were affected, the pseudo-hypertrophic form being present in two cases, but having given place in the older one (sixteen or seventeen years of age) to the atrophic form. It seemed to bear out the view of a mixed type. His question, repeated in another form, was, whether these cases always remained hypertrophic.

DR. DANA said he thought they died atrophic.

Large Lipoma Removed from the Region of the Mamma.—DR. R. F. WEIR presented a fatty tumor, weighing over seventeen ounces, measuring $6 \times 5 \times 1\frac{3}{4}$ inches, removed from the region of the mamma of a girl, twenty-two years of age, who had noticed it three years before. The specimen was of interest because of its rarity in this region. Gross alluded to four cases developing under the mammary gland, which was the particular situation of the tumor presented. At the suggestion of Dr. Thomas an incision was made along the edge of the mamma, the gland was lifted up, and the tumor readily enucleated. The following was the report of the pathologist:

The tumor which you removed yesterday from the mammary region of a patient at St. Luke's Hospital weighs seventeen and one-half ounces, and measures $6 \times 5 \times 1\frac{3}{4}$ inches; it has a smooth, rounded surface, is encapsulated, and in the capsule were seen distinctly some blood vessels.

The tissue, both to gross and microscopical appearance, is adipose. Very truly yours,

JOHN S. THACHER.

Gastro-colostomy.—DR. W. M. POLK related a case of gastro-colostomy (see p. 200).

DR. WEIR inquired how far the opening in the small intestine was from the duodenum, and whether the catgut rings had been recently made.

DR. POLK replied that, as nearly as he could estimate the distance, it was ten inches. The rings had been made and pressed for about four days.

DR. WEIR had asked the first question because most surgeons who were doing gastro-colostomy now went farther from the duodenum than formerly, in order to avoid traction. The second question was prompted by the fact that the ring had twisted, which had not been usual where they were made and pressed some days before use. The patient on whom he had operated for almost the same condition present in Dr. Polk's case, except that they did not know beforehand to what the decided stenosis of the pylorus was due, was still living, and at one time had gained thirteen pounds in thirteen weeks. In doing gastro-colostomy instead of Loretta's operation he departed somewhat from the custom, but this course was now being approved by German surgeons. He asked the President what was the present condition of this patient.

THE PRESIDENT said the case was reported four or five months ago as being in very good condition; his nutrition was excellent at that time, and introduction of the stomach-tube and fluid showed that while there was dilatation of the stomach, it was not great. It had undoubtedly diminished in size since the operation. The question then arose whether this dilatation was due to the state of the stomach before the operation, or whether it was due to subsequent stenosis, and whether the stomach could ever regain its former size. Answering the last question, he said he thought it could not; that such distention as had existed in this case, extending over a period of three or four years, the stenosis being the size of a quill, could never be repaired. Two or three weeks ago the man again returned, suffering greatly from various gastric symptoms, although his nutrition had been maintained. He weighed perhaps fifty pounds more than before the

operation. He had heartburn, eructations, and the evils which go with dilatation of the stomach, and the question was whether the dilatation was due to recurrence of stenosis or to distention from some other cause. If he should not improve under lavage and careful treatment, another operation might have to be performed.

Digestion of the Catgut Ring.—It was evident, the President said, that the catgut ring had been digested, and, as Dr. Polk had stated, it could not have occurred post mortem, since the autopsy was made fifteen minutes after death. There were two points to be considered in this connection: one was that possibly there had been no associated catarrh or glandular atrophy in the stomach, in which case one might expect normal or fair secretion of gastric juice, with sufficient hydrochloric acid to serve the purposes of digestion, and which would account for digestion of the ring. But this assumption was not necessary. Since there had been stenosis, and probably accompanying catarrh, there must have been marked lactic fermentation in the stomach contents, and the lactic acid in the presence of any pepsine would be quite sufficient to digest the catgut. It required only five times as much lactic acid as hydrochloric to do the same work with pepsine.

Dr. Polk said, in closing the discussion, that he followed along the jejunum until he got hold of a portion which could easily be brought out and kept out of the abdominal wound without any difficulty whatever, so that the trouble could not have arisen from not going far enough down; there was no traction. If the anatomical difficulties could be overcome, it would be much better to make the anastomosis on the posterior wall of the stomach, but he agreed with Dr. Weir that this would be very difficult.

Ovarian Tumor, with Anæmia, and Death by Thrombosis of the Pulmonary Artery.—Dr. Clement Cleveland related the above case (see p. 207).

A Rare Cause of Death.—Dr. Beverley Robinson asked whether, inasmuch as thrombosis of the pulmonary artery was an extremely rare cause of death, this was really a case of thrombosis or one of embolism.

Dr. Cleveland again read the symptoms, which included coldness of the extremities, disappearance of the pulse, very marked dyspnœa, and anæmia, and said it was evidently a thrombus of the pulmonary artery. The artery was examined for some distance.

Dr. Draper thought the history pointed to thrombus, not to embolus. He had seen a number of cases of thrombosis of the cerebral veins, and asked Dr. Biggs whether this was not a common location.

Dr. Biggs hardly thought the cases were common. He had seen a number of instances of thrombosis of the pulmonary artery in pulmonary tuberculosis, the thrombus not connected directly with the pulmonary disease, but supposed to be due to profound anæmia and weakness of the circulation. And, replying to a question by Dr. Robinson, he said they were not cases of secondary thrombus developed on an embolus.

Dr. Robinson said that in cases of thrombus due to weakness of the circulation, we might expect to find antemortem clot in the heart, about which there had been considerable dispute.

Dr. Biggs had recently seen a case where there was thrombus of the left renal, left splenic, and left pulmonary arteries, yet there was no thrombus in the heart. The heart was very weak; there was some change in the myocardium, the muscle was flabby, but there was no valvular lesion.

Case of Intestinal Obstruction.—Dr. W. H. Draper related the history of a case of intestinal obstruction which occurred in a woman, aged twenty-eight, admitted to the hospital April 7, 1890. There was a moderate wine habit, no rheumatism; since childhood she had had attacks of abdominal pain followed by diarrhœa, apparently not preceded by constipation; no previous pulmonary, cardiac, or renal symptoms; she had borne children, denied venereal history. For three months past the attacks of abdominal pain and diarrhœa had been more frequent; had also had attacks of vomiting of food and bile. The last two weeks the pain had been constant, except when relieved by morphine. During the severe attacks the pain extended up the back. The movements had been frequent. The patient had emaciated greatly, and lost much strength during the last three months. Her stomach had been washed out daily during that length of time. For two weeks she had been in bed. When admitted the patient was emaciated, pale, cheeks flushed, eyes bright, tongue fairly clean, no appetite, bowels loose, sleep poor on account of the pain, which she located most particularly just above the umbilicus; the belly considerably distended; marked peristalsis could be seen and felt at times; pulse small and weak, 120 per minute; respiration, 28, temperature, 97.2 F.

The urine contained a trace of albumin, a few hyaline casts. During her stay in the hospital until operated upon, on April 24th, by Dr. McBurney, the paroxysms of pain recurred frequently, requiring hypodermics of morphine. Nothing could be felt by rectal examination. The belly was distended, but not greatly. The distention was below the umbilicus; above it was quite flat. The peristaltic movements, when visible, were most marked in the lower portion of the belly, and there was a large coil of gut below which led Dr. Draper to suspect it might be the colon; yet he was disposed to think, from the flatness above and only slight distention of the bowel, that it was a coil of small intestine and that the obstruction was in the small intestine. The stools were small and ribbon-shaped.

The notes from the surgical ward stated that the operation was performed under ether; usual antisepsis. Stimulation hypodermically before, during, and after the operation. An incision six inches long was made in the linea alba, with its centre a little below the umbilicus. The small intestine was found enormously distended, resembling the colon. Constriction found some distance above the ileo-cæcal valve. It was not absolute, consisted of a contracted portion of the wall of the intestine itself. It was indurated, and the peritoneal coat sloughy. It was decided to make anastomosis between the intestine above and below the constriction, extirpation of the disease being out of the question owing to the emaciation and exhaustion of the patient. The intestine was so tense that the anastomosis had to be made between portions only three inches above and below the constriction. Strips of iodoform gauze were passed through the mesentery and tied around the intestine just beyond the points at which anastomosis was to be made, to prevent escape of fæces. An incision was made into the side of the gut at each of the points named, and into each opening a catgut ring (a modification of Abbe's rings) was introduced; silk sutures passed from each segment of the ring through the wall of the intestine, half an inch from margin of the orifice. The corresponding sutures from the two rings were tied together. The iodoform constriction band was then removed, the abdominal wound closed by silk sutures, no drainage; antiseptic absorbent dressing. Duration of operation, one hour and fifteen minutes. Shock was marked, and the patient became gradually weaker and died in the evening.

A formal autopsy was not permitted. The abdominal wound was opened and thorough examination made of the small and large intestines by Dr. R. A. Sands. The rings had held firmly, and there had been no escape of fecal matter. The small intestine was still much distended. In passing down from the pyloric end of the stomach to the ileo-cæcal valve, another partial constriction, of the same general character as that found during the operation, was discovered about three feet nearer the stomach than the other. In the lower constriction the mesentery was involved; it felt hard and knotty. The upper constriction was much less complete than the lower. The appearance of the portion of gut including

the constriction was carcinomatous, but a microscopical examination had not yet been made. The uterus was found retroverted and firmly bound down by adhesions.

Peristalsis as an Indication for Exploratory Incision.—Dr. Weir thought carcinoma of the small intestine was very rare, and it was still more rare to find it in two places. Regarding peristalsis, he had been able to recognize this through the abdominal wall in a few cases of chronic obstructive character, and had about concluded it should be regarded as one of the minor indications for an exploratory incision in such cases, as indicating that one had waited sufficiently long.

Dr. Draper replied that was true, yet he had seen cases of chronic obstruction of the bowels, of moderate degree, accompanied by visible peristalsis which went on a very long time, and the patients remained tolerably comfortable. There was not always severe pain, and in some there was no pain at all. In such cases opium favored action of the bowels, he supposed, by causing relaxation. He did not mean to say that the patients finally got well.

The Value of Injections of Water and Air in Diagnosis.—Dr. Robinson raised this question, and Dr. Weir said, regarding injections of fluid, that they were useful in diagnosis where the constriction was complete. Knowing the quantity of fluid which the gut contained, the site of the constriction could be estimated in this way.

The President said, regarding injections of air, that it was claimed if the constriction were complete the air injected would escape with the foul gases contained in the gut, and if the constriction were not complete a large amount could be injected.

The Significance of Ribbon-shaped Stools.—Dr. J. D. Bryant had seen a case to-day in which the question of intestinal obstruction was raised, and it had been suggested that the presence of ribbon-shaped stools pointed to an obstruction near the sigmoid flexure. That seemed to be the general impression, yet in Dr. Draper's case the obstruction was in the small intestine. The shape of the stools was here due perhaps to scarcity of fecal matter in the lower bowel.

Dr. Draper said the colon was small, being collapsed, and he supposed the stools retained this shape because slowly passed through the collapsed large intestine.

Dr. Robinson remarked that peristalsis was not always observable in cases like the one related, and the President remarked that he had observed peristalsis of the stomach in half a dozen cases of close constriction of the pyloric orifice.

Search for more than One Constriction.—Dr. Weir said there were several cases on record in which the surgeon had closed the abdomen after relieving one intestinal obstruction, and at death another was found. It taught the importance of examining the whole intestine.

A Case of Alcoholic Cirrhosis of the Liver in a Boy, Aged Thirteen.—Dr. H. M. Biggs related the above case (see p. 206).

Dr. Biggs added that he had seen with Dr. Jenkins four cases of death from acute alcoholism in boys, one of whom was aged five, one eight, and one ten years. The history in each was practically the same; they had taken a large quantity of liquor, remained unconscious six to ten hours, and died without regaining consciousness.

Dr. Dana said he had recently analyzed nearly four thousand cases of alcoholism appearing in Bellevue Hospital during about eighteen months, with reference to age, sex, etc., and while there were cases at all ages from twelve to seventy years, yet in none had death taken place below the twentieth year.

Dr. Draper remarked that he had seen a number of cases of cirrhosis of the liver in very young subjects. Recently he had had under observation a child of three years whose case had puzzled him considerably. The physiognomy of the patient was very suggestive of cirrhosis. It was very much emaciated, very anæmic, had pot-belly, marked abdominal veins, apparently a very small liver, and there was gastro-intestinal catarrh. The gastro-intestinal catarrh seemed to have been due entirely to inability to digest starchy food and milk. It was getting well on a diet of meat. The parents were gouty, but no other cause for cirrhosis.

Stated Meeting, May 23, 1890.

H. F. Walker, M.D., in the Chair.

The Prognosis of Lateral Curvature in Young Girls.—Dr. V. P. Gibney read a paper with this title (see p. 204). To illustrate practically the methods which his experience had led him to adopt for the routine treatment of lateral curvature in young girls, Dr. Gibney introduced a number of these patients, forming part of a large class now receiving special training at the Hospital for the Ruptured and Crippled. The exercises, based upon the Swedish movements, were designed to develop and accentuate the tonicity of any set of muscles indicated as required for definite support in counteracting a progressive curvature. The success of systematized muscular training was amply attested, the disease, when treated early, being in nearly every instance held in check and palpable deformity prevented.

Dr. C. L. Dana said he thought the general practitioner ought to be familiar with the accepted teachings in the treatment of these spinal troubles. It was only the other day that a patient was sent to his clinic suffering from chorea; he was also suffering from lateral curvature. A brace had been ordered and the information volunteered that unless it was worn the child would be incurably deformed. The speaker had only found a very slight curvature, and it had seemed to him that the treatment suggested was both expensive and unnecessary. Still the advice was given by a physician of large experience in such cases. Such treatment was, however, directly opposed to that of which Dr. Gibney had told them, and there seemed to exist entirely opposite views among men who were treating this class of cases.

Dr. F. P. Kinnicutt said he had seen the method advocated by Dr. Gibney carried out in one case with the most admirable results. The case had been one of grave import, so far as threatened discomfort and deformity to the patient were concerned. The method advocated was faithfully observed for a year under Dr. Gibney's instructions, with conscientious attention to detail, and the success in this case had been all that could be desired.

Dr. Whitman said the out-patient treatment of these cases at the hospital was rather a compromise. Where patients had no time to take the exercises, the practice was to put them in braces to relieve the pain and correct the deformity.

The President inquired if any arrangement could be made with any of the professional instructors in the muscular training to attend to private cases.

Dr. Gibney replied that there were in the city a few men and women engaged at this sort of work who could be trusted to carry out pretty faithfully any work given them. It must be remembered, however, that they all brought with them traditions from Stockholm, about muscles and so on, which they had learned from their professors, and no matter how they were instructed here, they were liable to drift into their own methods to the exclusion of what was required of them. It was the intention of the gentleman in conducting the classes at the hospital to establish himself in an office where he would be able to attend to private cases. They seemed to make it a *sine qua non* that the patient should be nude, but this the speaker had not allowed, as he did not believe it necessary after the initial observations of the deformity were made, at which time a course of exercises could be mapped out. In special cases the patients might be provided with tight-fitting shirts, such as were used in the application of plaster-of-Paris jackets. Replying to Dr. Dana's inquiries, he said that jackets of any kind were

detrimental in cases of lateral curvature but slightly developed. In those where the disease had advanced, and in which the ribs overhung the pelvis, braces did good service. If he found that patients did not take kindly to the exercise scheme, and it was evidently not worth while to persist in this course, he then recommended a plaster-of-Paris corset, merely to hold them where they were. As to the style of brace, he thought the Schaffer brace was a practical arrangement, and the Knight brace would also prevent the further development of the trouble; but he did not believe that the plaster-of-Paris jacket or corset would do so. If a patient wore a solid jacket or corset for a long time, thereby keeping the muscles constricted, it would be necessary to keep them developed by electricity to prevent the patients sinking more and more. In many cases the disease developed while the plaster-of-Paris jacket was crumbling. Then, to prescribe exercise one hour out of the twenty-four did not seem good in principle, and was no good in practice, because it was undoing in twenty three hours what was effected in one.

Hemorrhage in the New-born. — DR. E. L. PARTRIDGE read a communication on this subject (see page 202).

DR. A. H. SMITH said that the only case of hemorrhage in the newly born that had come under his notice had occurred from the bowels. He would like to know if the author of the paper had found anything specially useful in the way of treatment.

DR. PARTRIDGE replied that he had never adopted any particular medication because he had no confidence in the utility of such treatment in these cases. It was his aim to stimulate the child and get it as well fed as possible.

DR. KINNICUTT said that, as he remembered Winckel's cases, there was very much to point to the theory of infection in them, as they had occurred in close succession in the same hospital and with similar symptoms. The infants had become suddenly cyanotic and had collapsed, with subnormal temperature. There had been more or less jaundice and hæmoglobinuria.

DR. PEABODY had seen cases occurring in the Sloane Maternity Hospital in which those who were attacked with Winckel's disease had died in quick succession. The idea had then occurred to him of possible septic infection.

DR. PARTRIDGE, in reply to a question, said that hæmoglobinuria had occurred in twenty-four hours. The general appearance of the children had at first attracted attention, then the jaundice, and then the hæmoglobinuria had developed.

DR. DELAFIELD said that some years ago it had been his business to make the autopsies on babies dying in Bellevue. Many of these had been born in sugar-boxes, in ash-barrels, and so on, though others were born at the hospital. He remembered being struck by the fact that so many of them had presented extravasations of blood in the interior of their bodies, sometimes in one place, and sometimes in another. He had never known what it meant, and did not know now, but the discussion had recalled the fact to his mind.

Amenities of Medical Practice in South Africa.—A native medicine-man in South Africa has just had an experience which should convey a moral to his colleagues. The favorite wife of one of the chiefs in the district was taken very ill, and the medicine-man declared that the only cure was the ingestion of fat from the human heart. The chief on looking around him concluded that the heart of the doctor was most likely to furnish the amount of fat required, and ordered him to be killed, which order was promptly obeyed, and the fat of the heart given to the afflicted chieftainess. The other parts of the body usually eaten by cannibals were, it is said, eaten by the healthy members of the chief's household. The inhuman chief has been placed under arrest by the district magistrate pending a full inquiry by the Government officials. —*Hospital Gazette.*

Correspondence.

OUR PARIS LETTER

(From our Special Correspondent.)

THE PRESENT STATUS OF SURGERY IN OPERATIVE INTERFERENCE WITH GRAVE CASES—MORPHINOMANIA—SALOL IN SORE-THROAT.

PARIS, August 1, 1890.

THE growing tendency of treating medical cases surgically, or with the knife, particularly among the French surgeons, has called forth a severe remonstrance from Dr. H. Boens, one of the leading practitioners in Brussels, who has written a long letter to the *Journal de la Santé*, of Paris, on the subject. He began by remarking that the recent progress of surgery has been a good deal overrated. Since operators have understood that cleanliness is the first essential condition for the healing of accidental or artificial wounds, and that the wounded patient, or one operated on, instead of being drenched with tisanes, as was done formerly, is now supported at an early hour by good nourishment, they obtain numerous successes and they may undertake the most daring operations. As regards the operative art in itself, it has not made sensible progress. The difficulty of our profession is not to dissect or cut up patients, to open the chest or the abdomen and to sew them up again. This mechanical surgery is within the competence of all practitioners more or less experienced. The author remarks that the real difficulty and the supreme talent of men of the art consist more in preserving than in removing organs, viscera, and tissues; and making tumors disappear by appropriate therapeutical means, rather than violently extirpating them. It is thus that a number of so-called cancers of the breast, which are generally removed at once with the bistoury or with strong caustic, may be easily cured without any painful or cutting operation in a few months. The statistics of operations carried to extremes are not very reassuring, notwithstanding the incontestable progress accomplished in the hygiene or the salubrity of hospitals and the excellent care of the patients operated on. Every now and then medical journals report that a brilliant operation, performed with all the antiseptic arsenal in vogue, and with a surgical show destined to throw dust in the eyes of the spectators, has been immediately followed by the death of the patient. In speaking of cancers of the breast, Dr. Boens observes that they would become very rare if they were properly treated as soon as puffiness or engorgement manifests itself. The same is the case with goitre. A cutting operation is far from being without danger. At a recent meeting of the Belgian Academy of Medicine, a note was read by a hospital physician of Charleroi, who expressed himself in the following terms on the subject: "Thyroidectomy is a most serious operation, which should be considered the ultimate resource susceptible of saving the patient in certain cases of stenosis of the tracheo-artery brought on by the compression of the goitre. Its indications are the most delicate to determine, and surgeons are not yet agreed as to the choice of the method to be adopted." The author of the note then criticises the divers methods, discusses their indications, and points out their dangers and their ultimate consequences. He related a recent operation, which forms the conclusion of his memoir. It concerned a young girl, of sixteen and a half years of age, who was affected with a parenchymatous goitre which became dangerous for the life of the patient; dyspnœa was intense, and fits of suffocation were often repeated. He admits that the trachea was deformed by the goitre. He rejected the idea of ante-operative tracheotomy, on account of its little utility and its well-known dangers. The operation, by the procedure of Mikulicz, which he decided upon, was performed without any difficulty. Unfortunately the patient succumbed on the following day, in a fit of suffocation caused by the flattening, unmodified, of the trachea. Dr. Boens reports a similar case in a young lady of pro-

nounced lymphatism, in whom he prevented asphyxia, which appeared imminent, by the application of leeches, and reduced the tumor in six months by medico-chirurgical treatment.

That grave operations for medical cases are not always justifiable may be seen by the following observation: About eighteen months ago a well-known surgeon practised the removal of a tumor of the brain in a patient who had suffered from attacks of unilateral epilepsy for seven or eight years. The tumor was diagnosed to be situated in the convolution of Rolando. The spot for operating on having been marked out the surgeon trephined, removing a circle of about three centimetres. He then made a crucial incision into the dura mater, which was healthy, and cutting through the pia mater he incised the brain and removed the tumor, which was about the size of a small apple. A small drainage tube was introduced, antiseptic dressings were applied, and union by first intention was obtained without a drop of pus. During the night preceding the operation there had been thirty-seven epileptic attacks. On the night following it there were only five, and five or six days afterward there were none. Coma and delirium, with which the patient was affected, disappeared toward the tenth day, the complete paralysis of the two limbs, with which he was also affected, disappeared on the fifteenth day, the limbs gradually recovered their movements, and at the end of a month the patient completely recovered consciousness. All this seems very encouraging, but I have incidentally learned that the patient is relapsing into the same condition that he was in before the operation.

At a recent meeting of the Société Médicale des Hôpitaux, Dr. Huchard made some observations on three cases of permanent albuminuria in morphinomaniacs, and he is convinced that these cases of albuminuria are developed under the influence of the abuse of morphia, and that they appear to be due to arterial hypotension. As regards treatment, the author observes that a distinction should be made between morphinism and morphinomania. The morphinomaniac is a "cerebral," and he must be treated accordingly, then seclusion is indicated. In morphinism, on the contrary, the mental state is healthy, and seclusion should never be employed.

Dr. Ruault vaunts the use of salol in sore-throats. He cites several cases of severe tonsillitis in which suppuration appeared imminent and was prevented by the internal use of naphthol. This indication of realizing intestinal antisepsy was adopted by Dr. Gouguenheim, who related at the Congress of Laryngology the happy results obtained by him in anginas with the aid of salol (salicylate of phenol). According to this physician, salol acts efficaciously in acute anginas, whatever be the cause. It calms with the greatest rapidity the pain and the dysphagia, which are the most painful symptoms of these affections. In calming the pain it may abridge the duration of suppurated phlegmonous angina. It lowers the temperature. It diminishes, in nearly all the cases, the duration of anginas. To arrive at these results the dose should not be less than four grammes.

USE OF PYOKTANIN IN EAR DISEASE.

To the Editor of the Medical Record.

Sir: The Medical Record, with its characteristic enterprise, having in the issue of July 5, 1890, pp. 7, 8, through the interesting article of Dr. Adolph Kessler, drawn the attention of the profession of this country to the new bactericide, pyoktanin, it having been already tested with success in obstetrical, venereal, general surgical, dermatological, and ophthalmological practice, it occurred to the writer that it might interest your readers to know that it has been successfully employed in otological practice as well, where it seems to possess extraordinary power to subdue suppuration of middle-ear disease.

A brief history of several recorded cases will suffice to demonstrate the possibilities of this new addition to our therapeutic resources.

Case I.—A man, aged twenty, who had been affected with intermittent otorrhœa, both sides, for some time, when about seven years of age, and who had remained noticeably deaf in the left, slightly so in the right ear after the otorrhœa had disappeared, had been recently suffering from a recurrence of the otorrhœa for about one month in the right, one week in the left ear, preceded by an acute coryza. Both ears were the seat of constant dull pain and tenderness, with autophonous voice and mephitic discharge. The otitis was complicated with chronic atrophic naso pharyngitis, dental caries, and eruption of third molar teeth, constipation, epistaxis, nicotism, sniffing up salt water, etc.

The left membrana tympani was found perforated (about $\frac{3}{16}$ inch opening) in the anterior inferior quadrant, the anterior inferior middle third of corresponding canal wall being swollen and tender. The lower part of the right membrana tympani and the manubrium mallei were hidden from view by a soft polypus, which seemed to spring from a pedicle very close to, if not upon, the manubrium mallei. The relation of the parts making it difficult to ensnare it without including the bone, the polypus was removed with the cutting hooped curette, and was found somewhat double-lobed and about one-fourth inch in diameter. After hemorrhage had ceased, and both ears had been carefully cleansed, each was in turn filled with pyoktanin solution, 1 to 1,000, which was permitted to remain within the ear for ten minutes or more, the surplus solution being then carefully removed from the canal with a brush of absorbent cotton wool, the meatus being subsequently closed with a wad of this.

The discharge from the right ear, next day, was but slight and serous in consistency, appearing to be but what remained of the solution instilled before. There was no appreciable discharge from the left ear, the rim of the perforation of the drum-head of this ear appearing dry and cicatricial except at its anterior and inferior edge. The left canal was still swollen. There had been a slight epistaxis during the preceding night. A cleansing spray to nares, and pyoktanin solution to both ears were introduced, and an aperient prescribed. On the day following there was no visible discharge from either ear, and the right ear felt perfectly well to the patient. Aperient continued. Two days thereafter, both ears feeling comfortable, a Blake's paper disk was applied to the perforation of the left drum-head, where it has since remained. There has been no return of otorrhœa or subjective aural symptoms, and the hearing of both ears has improved.

Case II.—A youth, aged nineteen, who had suffered for four years from otitis media purulenta chronica, both sides, following excessive diving, and who had been operated on for aural polypus, was compelled to leave college because of incapacitating deafness. The disease of the left ear had been partially subdued. General anæmia, crowding, and caries of the teeth, etc., had complicated the otitis. Both ears had a mephitic discharge, and the symptoms of antophonia. There was a slight perforation of Shrapnell's membrane of the right ear. The left membrana flaccida was perforated ($\frac{1}{4}$ inch opening), the margo-tympanicus (auditory plate) melted away, and the malleo-incus visible in the tympanic attic.

The right ear was cured at once, the left almost so within four months, with the ordinary remedies. The slight discharge persisting in the left ear, with other phenomena attending aural polypoid growths, disappeared within several days after removal of a polypus, then invisible, through the perforation from the attic, by pneumatic pressure, the air being pumped from the sealed external auditory canal. The attic remained dry for one month, when on undue exposure to a draught of cool air a severe acute coryza developed and a subsequent recurrence of his otitis media, with otorrhœa, left side. After waiting one week without treatment, and the trouble increasing with progressive deafness, medical assistance was sought.

The ear having been carefully cleansed, pyoktanin solution, 1 to 1,000, was instilled into his ear for the first time, being allowed to remain there in about ten minutes, some of it having been forced into the attic through the atrium and Eustachian tube by pneumatic pressure until the air following had been heard to escape into the nasopharynx, the surplus solution then being removed from the canal with a brush of cotton wool, and the meatus subsequently closed with a wad of this. There has been since that day no evidence whatever of inflammation. It should have been previously mentioned that the patient had so far regained his hearing during the early treatment as to resume his old place at college without further embarrassment.

The preparation used in the above cases was the pyoktanin cœruleum of E. Merck, of Darmstadt, prepared in tablet form, each tablet containing 0.10 gramme pyoktanin.

Very respectfully yours,

ROBERT BARCLAY, A.M., M.D.

3211 LUCAS AVENUE, ST. LOUIS, MO.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 10 *to August* 16, 1890.

STEPHENSON, WILLIAM, Captain and Assistant Surgeon, now on duty at Columbus Barracks, O. By direction of the Acting Secretary of War, is assigned to temporary duty at Jefferson Barracks, Mo., during the absence on leave of Daniel G. Caldwell, Major and Surgeon, and will report accordingly. On the return to duty of Major Caldwell, Captain Stephenson will rejoin his proper station. Par. 2, S. O. 176, A. G. O., Washington, D. C., July 30, 1890.

CALDWELL, DANIEL G., Major and Surgeon. By direction of the Acting Secretary of War, granted leave of absence for one month and fifteen days, to take effect about August 15, 1890. Par. 1, S. O. 176, A. G. O., Washington, D. C., July 30, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 16, 1890.

WALES, P. S., Medical Director. Detached from Medical Examining Board and ordered to resume present duty at the Museum of Hygiene.

AMES, H. E., Passed Assistant Surgeon. Ordered as member of Medical Examining Board in addition to present duty.

SAYRE, J. S., Passed Assistant Surgeon. Detached from the Navy Yard, New York, and ordered to the Ranger.

NORTH, J. H., JR., Assistant Surgeon. Ordered to the Navy Yard, New York.

BARBER, GEORGE H., Assistant Surgeon. Detached from the Receiving Ship Vermont and ordered to the Pensacola.

VON WEDEKIND, L. L., Assistant Surgeon. Detached from the Pensacola and ordered to the Vermont.

AUZAL, E. W., Passed Assistant Surgeon. Ordered to temporary duty at the Naval Academy, to examine candidates.

FITTS, H. B., Passed Assistant Surgeon. Detached from the Pinta and ordered to proceed home and wait orders.

STONE, E. P., Passed Assistant Surgeon. Detached from the Independence and ordered to the Pinta.

WHITFIELD, J. M., Assistant Surgeon. Detached from the Monitors and ordered to the Naval Hospital, Norfolk.

AYERS, JOSEPH, Surgeon. Ordered to the Naval Academy to examine candidates for admission.

BRIGHT, GEORGE H., Surgeon. Ordered to Naval Academy to examine candidates for admission.

SMITH, GEORGE T., Assistant Surgeon. Detached from the Naval Hospital, Norfolk, and ordered to the Independence.

WHITE, S. S., Passed Assistant Surgeon. Detached from the Marine and ordered to the Naval Rendezvous, San Francisco, Cal.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 16, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	40	10
Scarlet fever	28	5
Cerebro-spinal meningitis	3	3
Measles	114	9
Diphtheria	39	12
Small-pox	0	0
Varicella	1	0
Pertussis	11	15

A Three-year-old Smoker.—Dr. Walter F. Morgan, of Leavenworth, Kan., writes: "*Apropos* of the case of a four-year-old smoker, reported in your issue of the 26th ult., allow me to state that here in the West, the reputed paradise of the 'young man,' we have beaten this record. Olly A——, when six months of age, is said to have had a 'run of fever,' followed by a hemiparesis. At three years of age he voluntarily began smoking his mother's pipe, and much preferred a cigar to a stick of candy. At four years of age another temporary illness caused him to reject tobacco, which, for the first time, produced nausea, and he has not since felt inclined to resume it. He is now about twelve years of age, and still shows a defective development of one side. Your suggestion regarding treatment in such cases, viz., 'counter-irritation in the shape of a daily spanking,' cannot be much improved upon, perhaps, unless extended to the foolish parents, who, by example and heredity, produce these 'youthful monsters.'"

Hysterical Contracture Cured by a Box on the Ear.—The following is related of the famous French surgeon Dupuytren (*Lyon Médical*). He had been summoned one day to attend a distinguished marquise who was suffering from dislocation of the jaw. On entering the room he walked up to the lady, and without uttering a word gave her a vigorous slap on the face. The marquise immediately called out to her servants to show the doctor to the door. But in giving her order, much to her surprise, the marquise discovered that she was cured of her dislocation. Moral: A box in time saves the chloroform.

Is Fair Hair Becoming Extinct?—A recent issue of the *British Medical Journal* prints a long editorial article devoted to this burning question. It concludes as follows: "On various grounds, therefore, it would seem as if the fair hair so much beloved by poets and artists is doomed to be encroached upon, and even replaced, by that of darker hue. The rate at which this is taking place is probably very slow, from the fact that nature is most conservative in her changes."

A Louisville doctor, aged eighty-one, has just married his sixth wife, aged forty-one.

Uterus Duplex.—Dr. G. Eduard Buxton presented to the San Diego (Cal.) County Society a patient with this malformation, which was demonstrated to the members present by individual inspection. In relation to the case he said the girl was nineteen years of age, and had been brought from the country to be treated for "whites," which had troubled her for eight months but had been profuse for four. Was engaged to be married, but health being so poor this had been postponed. Had lost weight, no appetite, some cough, was pale, bloodless, and hysterical; her countenance had the peculiar hue of chlorosis; complained of much pain through pelvis; had frequent and painful micturition. The pudendum, as seen, was swollen and covered with a thick, yellowish, foul-smelling discharge, and venereal disease was suspected; but on seeing her again, the active inflammation having in the meantime been reduced by appropriate remedies, the hymen was found intact and only after applications of cocaine could the little finger, with difficulty, be inserted. Injections for vaginitis and constitutional treatment were continued for some time without an arrest of the leucorrhœa; and the virgin-size speculum was introduced a number of times for purposes of examination and applications without discovering anything abnormal. But finally noticing a flake of matter adhering to the side of the vagina, and apparently partly covered by a fold of the mucous membrane, this was lifted up on a probe and the opening into another passage appeared, which, on investigation, proved to be another vagina with separate and distinct uterine os and canal termination: in other words here was a double vagina and uterus. And now the slow progress made in treatment was explained; a single vaginitis had been treated while a double one was to be cured. There is but one ostium vaginæ, and nothing externally to hint at the double condition within. The opening to the extra passage is on the left side and about an inch behind the hymen. This malformation, we are told, is due to an arrest of development in the ducts of Müller; instead of a union or coalescence of these ducts, each duct grows by itself, uniting at the median line; but absorption of this central wall fails to take place. Eisenmann, copied into all the books, shows a double all the way, with double hymen.

Skene speaks of a case of double uterus he attended where the right had borne three children, while the left was virgin. She had been attended in her confinements by three different physicians, none discovering the malformation.

Barnes mentions a case, attended in consultation, with severe puerperal convulsions. The gentleman in charge could touch the presenting head, but, he says, "When I tried, I found a dense fleshy septum between my finger and the head, although it was quite clear that my finger passed into the os uteri. At last, following my friend's guidance, I also got my finger on the head; and here I ascertained that there were two ora, each leading to distinct uterine cavities, one of which contained the child, while the other was empty. It was necessary to deliver by craniotomy."

In the Heidelberg Museum there is a double uterus with double vagina taken from a woman who died after labor. At her labor two distinguished physicians attended; one declared the woman was not pregnant, the other that the head was in the os uteri. One had examined the left vagina, the other the right.

Emmet speaks of retention of menses on one side, in this condition, as presenting a very puzzling case for diagnosis.

In a late number of the *New York Medical Journal* Dr. Currier reported a case of double uterus in a woman married eight years and who had borne five children; this condition of uterus was only discovered during an operation in which the abdomen was opened and the uterus exposed.

In the discussion that followed before the Academy of Medicine, Dr. Murry said two cases of double uterus had come under his observation, and there had been no interference with the course of labor. The practical question in this particular case, Dr. Buxton said, is what bearing does it have on marriage and maternity? Her mother asks can she marry? And the physician inquires, would she likely become pregnant in one or both sides; would she go to full term, or would the rudimentary organ abort or rupture? If she safely reached labor would this vaginal septum obstruct; if so, should it be divided, and when—now, before marriage, at the beginning of pregnancy, or when labor should demonstrate that such was necessary? The subject elicited a very general discussion; just such a case never had been seen by the members present. Dr. Doig had under treatment a patient, the mother of eight children, whose vagina is divided by a septum in the median line, beginning back of the ostium vaginæ and extending to within a short distance of the uterus, but leaving that organ free and unattached; the uterus itself being single throughout. The septum in this case seems to offer no obstacle to labor.

The members thought in the light of statistics we should not be justified in discouraging marriage in a case of this kind, nor interfere in any way with the due course of nature until such time as it should become apparent that aid was necessary.

In closing the discussion Dr. Buxton called attention to the statement by Barnes: "If labor was found obstructed by such a septum, there should be no hesitation in dividing it." And to Lusk: "It is still undecided whether double uterus be a cause of abortion and of premature delivery; ordinarily the symptoms and course of pregnancy are unaffected by this malformation, although we sometimes have tedious labor from uterine atony, and post-partum hemorrhage from atony or attachment of placenta to septum, which being imperfectly developed does not contract."

In a recent number of the *New York Medical Journal* Dr. Goelet mentions a case in which he had dissected out the vaginal septum and was inclined now to question its expediency. And also to a paper on this subject read by Dr. Dunning, of Indianapolis, before the Obstetrical Section of the American Medical Association, at its last meeting, based on a case he had accidentally discovered in treating a case of abortion; he said it had been usually supposed that the mortality in such cases was great after abortion or labor at term, but he showed the contrary was true; hemorrhage in this condition was not so dangerous nor so common as had been heretofore believed.

Dr. Buxton said he had not felt it to be his duty to place barriers in the way of this young person's marriage, and had advised the mother to sanction it.

The Arrogance of Quackery.—The audacity of the quack under the quasi-protection of a free government is a political force in many parts of the United States. As applied to the State of Illinois, it is said to have forced the retirement of Dr. Rauch from the State Board of Health, through the demands made upon the Legislature of that State by the venal rural press, which subsists on quack advertisements. The quack influence dominates the law-givers and threatens to nullify the work of the health authorities for the protection of the public. For ten years Dr. Rauch has been a thorn in the side of the fraudulent diploma mills, of the advertising nostrum-makers, of the travelling charlatans, and, finally, of the quack-fed newspapers, and now they have united in one supreme effort to drive him out of official position. He has waged unrelenting warfare with them; but he was never able to crush them. And now they seem to have grown stronger than he. In Oregon the newspapers, or some of them, have raised a clamor against the State Examining Board, because of its refusing a license to an advertising quack of the old Buchanan stamp, and the latter has been induced to return to the State and measure swords with the State board. If he succeeds in his contention he will be en-

abled to continue to practise at Portland, and that, the papers rejoice to say, will be equivalent to $50,000 annually expended in their advertising columns. This, from their stand-point, is worthy of an effort. But these papers never stop to inquire whence these dollars must ultimately come—viz., from the pockets of the suffering public—nor how much of malpractice and suffering and damage must incidentally be incurred in order that the quack may get the means to advertise thus lavishly. The audacity of quacks is also illustrated by a recently reported trial at Pittsburg. The defendant, one of the "no-cure-no-pay" species, had, it is charged, caused the death of a man, whose widow brought suit for damages. He entered the plea that he could not be held, for he was "no doctor." The court rightfully resented this monstrous plea and committed the case to the jury to pass upon the facts.—*The New York Medical Journal.*

Doctors Make Poor Patients.—The practice of medicine ought to make its professors the most sympathetic and tender-hearted of men, and so they often are. The spectacle of so much suffering, such helpless, hopeless misery, cannot be without a most salutary influence on the medical attendant. He enters the sick room full of spirits; his life is one of constant variety, and he knows that whatever his clients may think and feel when in perfect health, when ill they hang on his words, attach almost superstitious importance to his lightest opinion, and credit him with powers and foresight which he would be the first to disclaim. Herein we think lies much of the doctor's immense influence for good: he can cheer, comfort, and sustain; he often knows from long experience that the ailment, which to the sufferer seems so hard to bear, and which is thought to be attended with extreme danger, will speedily run a simple course, and that in two or three days the patient will be convalescent, and will be looking forward to a speedy return to his ordinary life. The only exceptions are those comparatively rare cases in which recovery is not to be looked for; but these bear a small ratio to the whole number of the sick. Perhaps, too, we might exclude the rather large class of fashionable invalids, who, without much the matter, enjoy the importance of illness and appreciate at their full value the doctor's friendly visits and his little attentions. But one class of the sick can seldom find any consolation from the doctor's visits, and that class is the medical. Whatever confidence the sick physician may have in his brethren's skill and knowledge, he cannot be cheered by the latter's encouraging words, for he himself knows so much that he will not confound a slight cough with the last stage of consumption, and a little indigestion with heart disease; but, nevertheless, when he is conscious that he is in the first stage of a serious and protracted illness; when he suspects or has ascertained that his complaint is one which can only have one termination, the grave, then, however encouraging his colleagues, however grateful their sympathy and welcome their special skill, he looks far beyond the present, and understands with a clearness which not one layman in a thousand can fortunately pretend to, that suffering, and possibly financial ruin, and finally death, await him.—*The Provincial Medical Journal.*

Naregamia, the New Expectorant.—Dr. Schoengut, of Vienna, has recently employed a tincture prepared from the bark of naregamia alata, which is a shrub indigenous to India. It is necessary to dilute the tincture. He recommends the following:

℞. Tincture of naregamia..... ..... ♏ xvj.–xlv.
Cherry-laurel water ..... f℥ ij.–f℥ j.
M. Sig.: Ten drops every hour.

In the twenty-four cases in which Dr. Schoengut employed the tincture the expectorant action of the drug was manifest in every case, especially in those characterized by scanty secretion and severe cough, or where the expectoration was viscid and stagnant. In cardiac affections, accompanied by catarrh of the respiratory tract, the tincture acted beneficially. Good results were obtained by its use in cases of pulmonary emphysema. It is claimed that naregamia renders the bronchial secretion more fluid and less viscid. The improvement in the expectoration is followed by diminution of the respiratory difficulty. Circulation and digestion are not affected by the drug, which has no toxic action whatever.

In the Office of the Wrong Specialist.—A physician whose specialty was skin diseases one day saw a patient enter his office. "Strip off your clothes!" commanded the physician. "But, doctor!" expostulated the patient. "No buts!" exclaimed the doctor, who was quick-tempered; "do as I bid you." The patient doffed his clothes and stood naked before the dermatologist, who, examining him closely, remarked: "My good sir, I can detect no affection of the skin in your case." The patient smiled, and replied: "True, doctor. I came to consult you in regard to my eyes."—*Cincinnati Lancet-Clinic.*

An Easy Way to Raise a Reputation.—A South Carolina physician, asked why he located at Monclova, said: "It is a first-rate place for a doctor. If a man is sick all you have to do is to tell his friends (no matter whether the affair is serious or not) to go to a priest and have him confessed and prepared for death. If he dies they will say: 'What a good doctor he is, he knew he must die, and so had his spiritual interests attended to.' If he recovers they will say: 'What a capable physician he must be. The man was in the last extremity and prepared for death, and he cured him.' So in either event it is a first-rate place in which to achieve a medical reputation."

Looking Forward.—In an article by Dr. Danforth, published in the *Texas Courier-Record*, a strong plea for better wives and mothers is made. The doctor, whose Christian name is Grace, says that: "Many mothers, from a false delicacy, fail to instruct their daughters upon plain physiological facts that every girl upon coming to woman's estate is entitled to understand. A knowledge of the most sacred laws connected with our physical being is left to the tuition of companions and servants. Men realize that innocence and ignorance are not synonymous terms, but women still confound them. With the progress of our present civilization our daughters demand better instruction than their mothers received, to make a more just discrimination between modesty and prudery. Unborn generations are demanding better mothers." Unborn generations apparently know what they are about down in flowery Texas. In this imperfect world of ours it is never too soon to reform. We wish the unborn generations success in their enterprise.

Revue Internationale de Bibliographie is the title of a new journal published under the direction of Dr. Jules Rouvier, of Beyreuth. It will appear six times each year, and will be a pure index of medical literature, similar to the *Index Medicus.*

A Blow at the Bagpipe.—

A dentist, it seems, has discovered
That those on the bagpipe who play
Run a very great risk of promoting
A premature dental decay:
Nay, the mouthpiece so scrapes the enamel,
And injures the structure beneath,
That he states that continuous piping
Is terribly bad for the teeth!

'Tis well; that the piper should suffer
Is nothing but fair, I am sure;
But what of the innocent victim
Who has to his piping endure?
'Tis surely high time that some doctor
Should answer this question most grim,
And tell us, respecting the victim,
The effects that the pipes have on *him.*

THE TREATMENT OF CERTAIN DISEASES OF THE NERVOUS SYSTEM BY SUSPENSION AND POSTURAL METHODS, WITH THE DESCRIPTION OF A NEW APPARATUS.

BY ALLAN McLANE HAMILTON, M.D.,

NEW YORK.

NEARLY eleven years ago I suggested to Dr. Lewis A. Sayre, of this city, the use of suspension apparatus in certain cases of transverse myelitis. He had for many years, as is well known, employed the apparatus which bears his name, and the plaster jacket, for vertebral disease; and I had myself seen its skilful application by him in more than one case of compression myelitis due to Pott's, but I am not aware that he had systematically suspended the patient without the subsequent application of the cuirass. At this time, and afterward, I was in the habit of using postural methods in the treatment of inflammation of the spinal cord, the body being inclined in such a way that there was more or less spinal extension, while the feet were strapped to the foot of the bed. This was before the contributions of Langenbuch and others were made, in which nerve-stretching was advocated, and before the method of Volckmann had been published. My success in many cases was most encouraging, but I have never reported my experience except orally to several medical friends. It would be a work of supererogation to refer, except in the most passing way, to the active use of suspension for the treatment of nervous diseases, which is hardly more than a year old. During the year 1889 this method was tried by a host of French, German, and American neurologists, and by Motschutkofsky, of Odessa, who really appears to have been the first continental observer to give an explanation of the manner of relief, and whose last contribution, which has been translated into English, is certainly one to make us place great reliance upon this form of mechanical treatment. Charcot, in his original paper, which was one of the earliest, started an interest in this novel therapeutic procedure, and Eulenburg and Mendel were, in Germany, the first to publish a number of cases—about forty in all—which were subjected to nine hundred and seventy-five suspensions, and a decided diminution in the severity of symptoms in tabes, as well as other diseases was apparent. Subsequent German reporters have been more moderate in their praise of suspension, and some whose opinions are entitled to great weight have given it their emphatic disapproval. Mosler and Eisenlohr had known of no good results from suspension, except in one case, and Rumpf deprecated its use, especially in recent cases. The burden of evidence, however, goes to prove that suspension by the Sayre apparatus certainly effects decided improvement, and amelioration of all the symptoms of tabes, excepting the lost knee-jerk and ocular degeneration. In my analysis of the numerous reported cases I have been impressed with the fact that a great many are irregular and unsystemic, and it would appear that these are the ones most benefited. This conclusion has also, I believe, been reached by Abadie.

The accidents which may result from suspension by the head are too numerous to be disregarded, and putting out of the question the deaths that have resulted from carelessness or improper adjustment when the victims were alone, I believe—despite Motschutkofsky's optimistic assertion to the contrary—a great many disagreeable results may follow even the most careful suspension. Eisenlohr, in a discussion before the German Society of Naturalists and Physicians, referred to the fact that up to September 19, 1889, no less than seven cases of death had been reported in one journal alone. Gorecke reported the case of a man, aged forty, who was paraplegic, and who tried hanging, with the result that after the eighth suspension there was loss of speech and hearing and dysphagia, and though the treatment was discontinued he became blind—his thoracic muscles were paralyzed, and he died asphyxiated a short time afterward.

So far as I know there have been no very serious results reported in this country; but within the last few days I have been consulted, in regard to a tabetic patient, who on April 22, 1889, began suspensions, using Sayre's apparatus at home. He could only stand one minute on the toes at first, but became used to six minutes (gradually) without arm-straps. He was suspended twice a day sometimes. The suspensions seemed to benefit him at first, but produced sleepiness; face suffused during suspension. He had to be lowered very slowly, or he would have great pain along the spine and back of head. He thought he could walk better after a suspension. This was continued up to July 6th, when he had a very severe headache in the morning (the last suspension having been the night before). Pain increased on right side (top of head); went to bed; next day noticed an increasing paralysis of fingers of right hand.

On return to city he began suspensions again (which, however, had been continued while out of town two weeks), but often would go several days without any, and as winter came on, only had one a day. He could not stand so much either, only three minutes at a time. Before Christmas, 1889, he experienced great physical exhaustion on the least exertion; food did not seem to nourish—but took a great deal. The suspensions were stopped a few days before he was last prostrated, January 16, 1890. He passed no urine, except a slight overflow, from then until it was drawn off by catheter on January 27th. On evening of January 16th severe pain was experienced in right elbow, which, however, he had had before, and also involuntary contraction of left arm. There was great nervousness, of a nature which had never been seen before in the patient; sleep was impossible without a hypodermic of sulphate of morphia, which was given. This condition was followed by incontinence, and subsequently by right hemiplegia. It is needless to say the suspensions were stopped.

It would seem that suddenly developed loss of power of a paraplegic form is not uncommon. Motschutkofsky speaks of such an accident in one of his cases; and Blocq produced spasmodic paraplegia. A host of minor disturbances undoubtedly follow suspension by the neck and arms. Retention of urine, various sensory disturbances of a painful character, anæsthesia, hyperæsthesia, cramps, aggravated paræsthesia, and vertigo may be mentioned.

In one of my own cases a disagreeable vertigo, which lasted for nearly half an hour, followed a short suspension, even when the straps were perfectly adjusted; and in the case of a stout man, an inflammation of the scalp beneath the strap which passed below the occipital protuberance was produced, and for a time I feared phlegmonous complication.

The late Dr. Lewis Hall Sayre told me, a short time

before his death, that he had never known of any disagreeable accident to follow the use of this apparatus, and his experience was certainly very large; but it cannot be denied that others are more unfortunate. Several modifications of the original apparatus have been recommended, which more or less diminish the dangers, and I may refer to the elbow supports of Weir Mitchell, and the modifications of the lateral straps which form a part of Motschutkofsky's improved apparatus. The good effects of this treatment undoubtedly result, as Motschutkofsky has shown, by a direct elongation of the spinal cord and a change in its vascularity. This careful observer went so far as to remove a segment of the vertebral column, so that he might observe the change of position, if any occurred, in the cord. He determined the position in which the spinal nerve-trunks left the cord, and at a corresponding point externally made a mark of reference, and then suspended the cadaver. He found that when suspended the nerves became nearly vertical, and there was an elongation of the cord of from 3 to 4.5 ctm.; and he also discovered that there was a decided tension of the spinal meninges, with an increase in the amount of the cerebro-spinal fluid. The undoubted extension, which was manifested in a variety of ways as a result of the early experiments in stretching the sciatic nerve, go to show that even this rude accomplishment of the purpose in an imperfect manner was occasionally attended by beneficial results in tabes. Volckmann's method, which Motschutkofsky used in one case where neck-suspension was impossible and dangerous, because of dilatation of the heart and arterial sclerosis, is, virtually, an extension of the sciatic nerves. The patient lies on an inclined plane, cords are fastened to the feet and passed over pulleys at the foot of the bed. To the cords are attached ten-pound weights.

Spinal extension has also been effected by the mechanical method of Hessing, which seems to be rather popular in Germany. The apparatus consists of a tightly fitting cloth jacket, which exerts slight and gradual traction of the spine, but it is a tardy and slow method of procedure, and must be worn for several years. Jürgenssen reports very decided improvement from its use in tabes. In his case the vesical and rectal disturbances of tabes and the lancinating pains disappeared. There was an improvement in sleep, and the gait was less awkward, and he has even known of the return of the knee-jerk when it had been abolished. Erb has used it with gratifying success in cases of multiple sclerosis and transverse myelitis, and Vierordt had known the most excellent results to follow its employment in a patient with spinal disease, chiefly expressed in unilateral hyperæsthesia.

Some months ago I conceived the advantage of a more safe and equally effective method of suspension. This consisted of a movable inclined plane, the patient's feet being fastened to one end so that extension was made when the head was lowered. Acting upon my belief and previous experience that more simple methods could accomplish the same purpose as the complicated suspension apparatus, I had a rough apparatus constructed which is still in daily use. It consists of a pine board six feet six inches long, eighteen inches wide, and one and one-half inch thick. Midway between the ends, upon the under surface, are fastened on either side two iron trunnions, which work in bearings fastened to a stout framework about three feet high. A system of hooks and cogs permits the operator to place the board at any angle, or the patient to regulate his position. Since I have used this contrivance I have had no disagreeable effects whatever from suspension, and the resulting benefit has been just as great as formerly and the trouble has been far less.

I will not weary the patience of my readers by detailing published statistics of the encouraging success of suspension in tabes, but will briefly allude to five illustrative cases.

Analysis of Five Carefully Observed Cases of Tabes which were Treated with Suspension.—Case I.—Male; syphilitic; first seen in advanced second stage. Sensory condition: Characteristic pains; plantar anæsthesia, chiefly on the right side; sometimes unconscious of the position of the great and second toe; knee-jerk absent; Argyle-Robertson symptom; atrophy of left optic nerve; no decided vesical disturbance; usually constipated; no trophic changes; ataxia marked in the right lower extremity. Total number of suspensions, one hundred and eighty; at first three times a week, and afterward every day; arm supports never used; after first five suspensions there was a total subsidence of lightning pains. The first suspension was made during an *accès morale* of patient; greatly benefited, and increased ability to walk. After first ten much less ataxia; relief of pain continued. After first fifty absolutely no return of pain; anæsthesia greatly diminished; more acute sense of location; regained color of skin, and muscular tone improved. Present condition: Nearly one year under treatment, interruption absolutely during trip abroad. No pain since early suspension; little or no anæsthesia; ataxia almost inappreciable; can walk with eyes shut; no return of knee-jerk; optic-nerve atrophy unchanged; Argyle Robertson symptom exists as formerly; patient is undoubtedly helped to a great degree; the motor and sensory disturbances reduced to a minimum and the psychic state of this man contrasts strongly with that of one year ago. He has taken no medicine.

Case II.—Male; history of syphilis; end of second and undoubted commencement of third stage; duration of the disease about eight years. Sensory symptoms: Gastric crises at long intervals; pains in lower extremities; an area of anæsthesia over the sternum and about the anus; finger-tips and soles anæsthetic; delayed sensation; reflex disturbances ceased, and absolute disappearance of knee-jerk on both sides; pupils both contracted as a rule and do not respond to light; atrophy in both fundi; micturition frequent; constipation. Trophic symptoms consist of loss of toe-nails and a tendency to subcutaneous ecchymosis upon the lower extremities; the leg muscles were atrophied, and there was a mere suspicion of knee-jerk of the right knee-joint; gait greatly embarrassed; imperfect co-ordination of hands. Total number of suspensions, seventy-nine; all by head alone; at first weekly, and after a month daily. No noticeable improvement after first five suspensions; after first ten he was certainly less ataxic, and the functions of the bladder were better performed, and not so much characteristic pain. After first fifty there was continued, but slow, improvement in crises; no pains of any kind; but the anæsthesia was quite as profound as ever. His gait was less awkward. He now walks much more steadily. His muscles and skin are better nourished and he is less depressed than in the early months of treatment. He has discarded his cane.

Remarks: The treatment of this case was undertaken without much hope of a good result; the sclerosis was much too general and too long-standing to look for any general abatement of symptoms, but I was impressed with very decided improvement in all the nutritive functions. He had taken iodide for a long time. The reflexes have continued absent, and the condition of the optic nerves remains the same.

Case III.—Male; cause unknown. No history of syphilis in second stage. The peculiar pains affect both lower extremities, and are especially severe in left thigh anteriorly; anæsthesia of both plantar surfaces. There are pains which shoot down the arms; knee-jerk gone; Argyle-Robertson symptom present. No defined retinal atrophy; vesical irritability; constipation. Trophic disturbances consist in frequent and irregularly distributed crops of herpes and painless loss of teeth. Both extremities are the seat of ataxia, and he cannot use his hands for holding his pen or performing any of the little necessary acts of everyday life. Romberg's symptoms.

Remarks: Total number of suspensions, one hundred and fifteen, which were daily from the first. After first

five there was some abatement of pain and disappearance of vertigo. After the first ten decided improvement in the use of the fingers. Could button clothing; finger-tips less numb; no pains in lower extremities. After first fifty there was a maintained and continued improvement in every way. After one hundred and fifteen suspensions I am impressed with the advantages of this treatment. The patient retains his urine much longer; walks more easily; has not had pain for some time; though this was at first of almost daily occurrence, notwithstanding the disease had advanced well into the second stage.

CASE IV.—Male; light syphilis twelve years ago. First seen at the end of the first stage. Stabbing pains in lower extremities which were largely dependent upon the weather; formication of toes; absolute loss of sexual power; knee-jerk can only be occasionally evoked, and then feebly; superficial cutaneous reflexes, however, seem to be exaggerated; no appearance of optic degeneration; irritability of bladder with spasm; lower extremities the seat of light ataxia; some swaying in walk; Romberg's symptom; forty-eight suspensions, daily from the first; immediate improvement in condition of bladder after first suspension. After first five, and since, there has been absolutely no pain, and after the first ten a noticeable improvement in diminution of ataxia, which has been maintained, and now he is apparently free from all symptoms. This is a remarkable case, from the fact that the symptoms had existed for several months and were rapidly deepening, as they sometimes do in traumatic tabes No medicine whatever was used.

CASE V.—Male, aged thirty-eight, of irregular habits; addicted to alcoholic excess; no defined history of syphilis; vague sensory symptoms; lameness of the ankles; stabbing pains through ball of right foot, occasional fulgurating pains in calves and thighs, with cramps, especially at night. Attacks of neurotic diarrhœa and abdominal crises; no knee-jerk; optic nerve degeneration; lower extremities are ataxic; gait characteristic; patient easily agitated, and becomes demoralized when startled. Eighty-three suspensions in all; at first every day, then three times a week; hung with the arm support. After first hanging there was a feeling of better security, and less ataxia. After tenth hanging this was manifest to a great degree. He has had little or no pain since the first hanging. Condition after the fiftieth suspension: Walks firmly; little or no ataxia present; goes down-stairs without difficulty, and walks without a cane. The muscles are firmer, and there is very little difficulty in progression. He can stand with his eyes closed. The condition of the reflexes and fundus is unchanged.

In all these cases the suspensions averaged three minutes at first, and later they were protracted to eight or ten.

Besides these five cases, I have employed suspension in many others which were atypical or only occasionally seen. The results were, as a rule, encouraging, although there were many occasions where the treatment was followed by no relief.

My experience goes to show that suspension is far more beneficial in a number of functional and irregular conditions than it is in some of the diseases for which it has been most highly recommended, and, in fact, in those neuroses in which there is an hysterical element it has been, in my hands, exceedingly useful. I have treated six cases of traumatic hysteria, due to railroad accidents or falls, and am convinced that not only has it been of service in developing a state of expectant attention, but in some cases of spinal shock, with incipient disease of the cord it has promptly mitigated or removed the symptoms. One of my most satisfactory experiences with suspension was in a case seen in consultation with Dr. William M. Polk. The patient, a young married lady, was thrown from her carriage several years ago, striking upon the left occipito-parietal region, and her body was bent in such a position as to suggest to those who picked her up that her neck had been broken. She was unconscious for several hours, but improved, and after a long convalescence was able to lead an exceedingly uncomfortable existence. Besides violent pain in the left occipital region, which was at times neuralgic in character, she complained of almost constant pain at points corresponding to the situation of the second and fifth dorsal vertebræ, which at times extended anteriorly, with crises of epigastric pain which occurred without relation to the condition of digestion. She was unable to move about or take any exercise, and her social duties had for several years been almost entirely disregarded. When I saw her she was thin, pale, and badly nourished, and sat in a constrained position, her body being bent forward as if she had vertebral caries, and rotated her head with difficulty. Her knee-jerks were more active than normal, and she complained of areas of cutaneous hyperæsthesia, especially of the right lower extremity. Both superficial and deep pressure upon the dorsal spine produced distress, and she could not sit upright without great discomfort. I recommended suspension, and there was an almost immediate improvement. Sayre's apparatus was used seventeen times, making the suspensions by the head alone, discarding the arm supports, the length of the suspensions varying from twenty seconds to three minutes. After the second suspension there was great diminution in the pain, and a feeling of mental confidence which was very markedly in contrast to the previous psychical state, and as the visits were continued I was able day after day to note a slow but sure recovery of normal health, the patient at the end of the month walking with a regular carriage and firm step, gaining in color and flesh, going into society, and attending to her long-neglected domestic affairs. In this as well as the other cases the amelioration was prompt, and I could not escape the conviction that the spinal extension was entirely responsible for the improvement.

I have also used my own apparatus in three cases of more or less diffused neuritis, one case being of rheumatic causation, one of unexplained inflammation of the brachial plexus, and the third a traumatic case, and all were helped. One of the last cases in which I have used this extension apparatus was of meningo myelitis of specific origin, which yielded to a certain point to the iodide, but a tetanoid paraplegia of a light grade obstinately remained. The sensory features of the man's condition was an intense causalgia of the plantar surfaces, and, despite electrical treatment and massage, there was little or no improvement. Almost after the first day the apparatus was used there was a manifest gain, the spastic gait being less noticeable, and after daily applications for two weeks the patient declared that he could use his lower extremities with greater freedom than for months before. The sensory disturbance was also benefited. Bearing in mind the advantages of the postural method in certain vascular disturbances of the brain, I essayed its use in anæmic headaches, suspending the women by their heels for periods varying from three to ten minutes every day. There was no resulting embarrassment or discomfort, even when the treatment occupied the longest of these periods, and I was unable to observe any great difference in the cerebral circulation. The clinical results were certainly encouraging, and in one woman with a condition of pelvic derangement, in which ovarian dislocation was a feature, this, as well as cerebral disorders, was helped.

A Test of Virginity.—In the Middle Ages, when men were perhaps more suspicious than they now are, it was a not uncommon practice of the groom to demand proof of virginity from his future bride. This was obtained in a perfectly satisfactory manner, and without offence to the young woman's modesty, by having her blow out a candle. If she succeeded in doing so at a single puff her honor was vindicated, but if she failed she had sinned, and as many puffs as the candle-flame resisted so many had been her lapses from the path of rectitude.

THE IMMEDIATE REPAIR OF INJURIES TO THE PELVIC FLOOR.[1]

By IRWIN H. HANCE, M.D.,

NEW YORK.

EVERYONE must concede that lacerations of the pelvic floor do occur. A large number of these are not attended to at once, or the operation is unsuccessful, or only a skin perineum is formed; if the latter accidents happen it is, in my opinion, due to the fact that internal vaginal sutures are not used. My only excuse, therefore, in bringing up this time-honored subject before you is to show the necessity for internal suturing, and explain how it can be practically and easily done.

The results of antiseptic midwifery are such that one may now confidently expect to have an aseptic condition of affairs during the puerperium; if such be the case, why should the parturient with external and internal tears of the genital tract be compelled to put off for an indefinite period an operation which ought to be done at once, and if done will almost certainly be crowned with success? The time is past when physicians can excuse themselves by stating that the conditions are unfavorable and consequently you will not get a good or satisfactory result.

The operation, the technique of which I shall presently describe, may be used with slight modifications on lacerations through the sphincter; but as these are rare, I shall confine my remarks to those which do not extend into the rectum. My observations and results were obtained at the Nursery and Child's Hospital, where better opportunities are offered to study such a subject than can ever be the case in private practice.

Practically I observed three varieties of lacerations, which, however, varied greatly in the degree and extent of the injury.

1. A clean cut median laceration, starting at the posterior commissure and passing back, to a greater or less degree, directly through the middle of the perineal body. The simplest form of perineal lacerations and such as produce but slight inconvenience to the woman, even when quite extensive.

2. Lacerations of the perineum involving the skin in the median line, even as far back as the folds of the anus, associated with extensive injury of the posterior vaginal wall. This internal tear proceeds upward a little to one side of the median raphé; may, however, and often does, pass up on both sides of the vagina, in which event one branch of this jagged **V**-shaped tear is shorter and extends more obliquely upward than does the other.

3. Lacerations of the posterior vaginal wall without any rupture through the skin. These tears are usually **V**-shaped, one arm being longer than the other, the point of the **V** being situated at the posterior commissure.

The etiology of the injury does not concern us. I wish, however, to say a few words about the signs of an impending rupture. The first indication of any trouble is usually the escape of a little blood from the vagina, none having previously been observed during labor. An examination with the finger reveals a solution of continuity of the vaginal mucous membrane some little distance from the posterior commissure; this may occur from fifteen to thirty minutes before the head is born, if the vulva is narrow and perineum unyielding. As the head emerges, the laceration on the posterior vaginal wall grows larger, and with the birth of the head the skin ruptures. This I have repeatedly seen in normal cases, and also in forceps deliveries.

Œdema of the perineum may be present, but is not constant.

In other cases the first sign is a separation of the epithelial and other structures at the posterior commissure, almost immediately before the head escapes. This rapidly extends backward and produces a linear, clean-cut tear through the centre of the perineal body.

On other occasions there is scarcely any time for symptoms to present, for the head simply ploughs through the perineum by reason of the strength and rapidity of the uterine pains.

Finally, in a fourth set of cases the post-partum hemorrhage may be quite profuse, but the child is delivered without any external injury; careful internal examination will reveal quite extensive injuries to the posterior vaginal wall.

The wounds in all these cases resemble contused lacerated ones, and in repairing them their edges should be brought into direct apposition, and no raw surfaces or pockets left to allow of the formation of puerperal ulcers or other inflammatory action. This is best accomplished in the following manner:

All instruments are to be placed in a solution of carbolic acid; they are few in number, and include a medium-sized needle holder, pair of scissors, thumb-forceps, and tenaculum, with two sizes of catgut.

The hips of the patient are brought to the edge of the bed, the legs being held in the lithotomy position by assistants, or a sheet-sling passed around the neck, after which a vaginal douche is given, 1 to 3,000 bichloride. Draw back the labia on each side, and with the finger in the rectum advance the posterior wall of the vagina; by this means you fully appreciate the extent of the injury and bring into view the upper angle of the wound. This is the point where the first suture is to be inserted, and from here they are carried down to the external wound. Each suture must pass completely around the laceration in order to bring the deeper parts into close proximity. The internal sutures having been properly adjusted, external ones are now passed from behind forward, and the operation is completed by carefully closing the edges of the wound at the posterior commissure. This method applies to division 1, and most of the cases in division 2; when, however, the lacerations shoot off in two directions both sides must be sutured, the second arm being done in the same manner as, and after the first, after which the external wound is repaired. The nice point in this operation is in fitting together the parts which are to form the posterior commissure.

In division 3 the same rules apply; in exceptional cases it may be necessary to insert one or two buried sutures because of the depth of the wound. In one of my cases it was necessary to pass the first two sutures almost entirely by the sense of touch.

Catgut sutures (Nos. 3 and 2 of Am Ende's make) were always used for the deeper ones, and a lighter variety where the tension was not so great. Care should be taken not to draw them too tight, some allowance being made for subsequent œdema. Another douche is then given, iodoform dusted over the wound, iodoform suppository introduced into vagina, and antiseptic pad placed over genitals. The patient's legs are bandaged the first twenty-four hours.

The after-treatment may be summed up as follows: Catheterize the patient only when necessary. Introduce an iodoform suppository night and morning after the external genitals have been antiseptically cleansed. Use antiseptic pads to cover genitals. Open the bowels on the third day, earlier if there is any indication, and keep them open afterward. This was the routine practice during the last eighteen months of my service at the hospital, and is, I believe, still carried out.

Advantages: By commencing to suture at the upper angle of the wound the sides and edges are brought into perfect apposition from the start, and each subsequent suture is more easily inserted. You completely control all hemorrhage. The insertion of the sutures through the bruised vaginal tissues causes but little pain. The vaginal wound being closed the cutaneous one is much diminished as to depth and length, consequently not so many sutures are required. Frequently only one or two deep sutures are needed. It leaves no pockets for the accumulation of lochia or the formation of puerperal ulcers. A great

[1] Read before the Section on Obstetrics of the New York Academy of Medicine, May 22, 1890.

advantage is in the use of catgut, since this is absorbed and the patient relieved of all anxiety as to the removal of the sutures, which hold on an average seven days. Finally, it, in my opinion, restores the structure of the pelvic floor more nearly to its normal condition than appears to be the case with other operations. Some may object to it because it is slow and tedious; true, but if by giving a little more care and time to an operation which almost everybody considers necessary, you get better results, it is worth the trouble. The old idea and custom of allowing the wound to heal by granulation, and imagining that you thereby were getting a good perineum, has led many of us, I fear, into treating this injury in a less thoroughly surgical and antiseptic manner than would be the case if some other part of the body were affected. Others may object to it as unnecessary, the old simpler methods giving equally as good results. But they don't; this is shown by the frequency of the secondary operation, done after the primary has failed entirely or only united externally, and by the statistics of those who have thoroughly reported their cases. For example, of 103 lacerations Liebman's[1] results were as follows: Complete cure, 49; partial, 37; failures, 7. Steinmann:[2] In 98 operations complete cure about 44 per cent.; partial, 13 per cent. Bidder: Number not stated; complete cure, 47.6; partial, 26.9 per cent. Dr. R. C. M. Page[3] is the only one whose reports are very favorable. In his article on the "Immediate Operation for Lacerated Perineum," he states that at that time (1883) it was not done in the Maternity Hospital because it gave such poor results. His own successes were all in private practice. Of 100 cases he reports 90 cured, 9 improved, 1 failure; these were greatly due to the thorough antiseptic methods which were used before and after operation.

A final objection, which militates greatly against any immediate operation, is that the laity unjustly blame the accoucheur, holding him personally responsible for the laceration and attributing its occurrence to his inexperience or carelessness. This objection can be met only in part, first, by an honest acknowledgment on the part of every practising obstetrician; and second, by making the laity better acquainted with the facts in the matter. For this purpose I shall merely quote a few statistics of well-known obstetricians. Credé in 1,000 deliveries, in the Leipsic clinic, had 392 lacerations, 39.2 per cent. Fasbender, in the Berlin Maternity, gives the following: 300 cases; 67 lacerations, 22.3 per cent.; 150 primiparæ, 51 lacerations, 34 per cent.; 150 multiparæ, 16 lacerations, 10.6 per cent. Age—fifteen to twenty years, lacerations 30.4 per cent.; twenty-one to twenty-five years, 34 per cent.; twenty-six to thirty years, 38 per cent.; over thirty years, 50 per cent. M. Liebman: 1,064 cases, 170 lacerations, 15.9 per cent.; of these 471 were primiparæ, with 145 lacerations, 30 per cent.; 593 were multiparæ, with 45 lacerations, 4.2 per cent. K. Schroeder found 34.5 per cent. of lacerations in primiparæ, and 9 per cent. in multiparæ. Winckel gives 20 per cent. of perineal lacerations. Dr. F. E. Beckwith, of New Haven, in 200 cases, reports 62 per cent. of lacerations, 25 per cent. back to sphincter.

My own results, where all the lacerations were measured, were as follows: Primiparæ: 106 cases; 47 without any laceration, 44.3 per cent.; 6 with median laceration of ½ inch; 4 with median laceration of ¾ inch; 6 slightly torn through skin, no measurement; 5 slightly torn internally, no external tear; 38 extensive lacerations, of which 32 were repaired at once, 35 8 per cent. Multiparæ, 25 cases: 20, without any lacerations, 80 per cent.; 5 with lacerations; all of which were abnormal deliveries.

One may safely conclude from these varied statistics that fully 25 per cent. of all primiparæ have perineal lacerations.

[2] Geburt u. Wochenbett älterer Erstgebärender, Archiv f. Gynäk., Bd. xxii. 1883.

[3] New York Medical Record, December 1, 1883.

In searching the medical journals for these statistics I have only found one article in which the author advises the use of external and internal catgut sutures and gives his results. This was by Dr. H. Keller, in Bern, in an article entitled, "The Continuous Catgut Suture in Vaginal Lacerations,"[1] one quotation from which I beg leave to make: "Without exception I began the repair of the laceration in the vagina, since all lacerations begin there, and the suturing of the vaginal tear is done much better as long as the perineal tear is still gaping." His results were exceptionally good. Out of 42 cases he had 41 successful results, 97.6 per cent.; 2.4 per cent. failures. He reports 26 cases of Brüse, with 23 perfect results and 2 failures; 88.6 per cent.

To these I can add 32 more, with 28 of them successful, 87.5 per cent.; 3 fair result, 1 failure — case of post-partum hemorrhage with albuminuria. Thus of 100 reported cases there was partial or complete failure in only 7 per cent. Two of my cases I should like to briefly report.

Case I.—July 28, 1887. Lucy T——, American, primipara; pains very strong and frequent, driving head through perineum. External tear reached to the margin of anus, 1½ inch long. Internal tear V-shaped; one on right side of median raphé 2 inches long; one on left side of median raphé 1½ inch long. First suture introduced with some difficulty high up on right side, three more interrupted sutures closed the right-hand tear and three the left; four external interrupted sutures inserted; the fourchette was closed by one or two small sutures.

August 23d.—Result success.

October 4th.—Note perineum firm; grasps finger firmly; cervix badly lacerated; uterus anteverted. Patient has never had a bad symptom; troubled with leucorrhœa from cervical laceration.

Case II.—July 28th. Margaret V——, German, primipara. Vulva ring small; pains strong—good intermission. Delivery of head retarded; chloroform administered. Tear commenced internally; episiotomy done on left side, wound ¾ inch. Delivery accomplished without any further external laceration. Internally the tear extended down on right side alongside the rectal tube. Depth of this pocket, 3¼ inches; length of laceration, 2⅜ inches. To the left of the raphé extended another laceration more obliquely upward 1¼ inch in length; episiotomy wound, ¾ inch. First and second sutures on right side had to be passed almost wholly by the sense of touch; as they did not embrace all the structures two deep-buried interrupted sutures were inserted, after which two more were introduced and closed this branch of the laceration. Left side of tear was closed with three sutures; a pocket was left between the point of junction of these two lacerations and the skin, which was closed by a buried suture. One suture through episiotomy wound and some small superficial ones at fourchette completely restored the pelvic floor. Varicose condition of the perineal vessels. The result was a success.

August 29th.—Cicatrix on right side measures 2¼ inches; its highest point being not more than 1 inch from cervico-vaginal junction. Cicatrix on left side, 1¼ inch. Per rectum, a sound perineal body is found to exist. Cervix not torn—uterus somewhat enlarged and retroverted.

The results in these two different types of cases, which were about as bad as they could have been, did not surprise me, because I had by that time reached a point where I was confident of success. Such will, I am certain be your results also, if you will but give the operation a trial, paying especial regard to all antiseptic details.

A Homœopathic Dispensary is building in Boston. It will cost about fifty thousand dollars.

A NOTE UPON DISTURBANCE OF THE SENSE OF TASTE AFTER AMPUTATION OF THE TONGUE.

By FREDERICK PETERSON, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK HOSPITAL FOR NERVOUS DISEASES, BLACKWELL'S ISLAND.

THE distribution of taste-fibres with certain of the cranial nerves has long been a difficult problem for the physiologist and neurologist, and the intricate paths for gustatory sensations are not as yet conclusively determined. It is probable, however, that although there are taste-fibres in parts of the peripheral course of the fifth and seventh nerves (chorda tympani) destined for the anterior portion of the tongue, and others in the peripheral distribution of the ninth nerve supplying the posterior linguo-faucial areas, all of these gustatory fibres ultimately unite through the mediation of several ganglionic anastomoses to enter the brain together with the root of the fifth nerve.

Yet this is not the only puzzling feature of the taste apparatus. For instance, the final taste-filaments are distributed not only to the tongue, but to the soft palate and palatine arches; and another peculiarity is that the sense of taste, like that of touch and sight, is composite, so that fundamentally we recognize at least four, and perhaps five sapid qualities, viz., sweet, bitter, sour, salt, and the galvanic taste. Upon careful examination minute areas are found in which one of the qualities, sweet, bitter, sour, or salt, is perceived, and not any other, but the precise demarcation of these areas has not been definitely determined, and indeed probably varies widely in individuals. It is generally assumed that bitterness and sweetness are better perceived by the posterior part of the tongue, and sourness and saltness by its tip and edges. Almost nothing is known of the differentiation of sapid qualities by the soft palate and palatine arches. We are justified in believing that this physiologicial differentiation of the four qualities argues for a differentiation of anatomical structure, if not in the conducting fibres, at least in the terminal gustatory bulbs. Oehrwall,[1] who has made the most complete and latest contribution to the study of taste, carefully tested 125 papillæ upon his own tongue. All of them perceived touch and variations of temperature. Among these, 12 reacted to tartaric acid only; 3 to sugar acid only; 12 to sugar and tartaric acid only; 7 to quinine and tartaric acid only; 4 to sugar and quinine only.

In a matter still so obscure as the distribution and course of the gustatory parts, any study that will throw even a very feeble additional light upon it is welcome. Hence I take the liberty of reporting briefly the results of testing the sense of taste in two adult men whose tongues had been completely removed for epithelioma. Both patients were operated upon by Dr. James E. Kelly, at Charity Hospital, to whose courtesy I am indebted for the opportunity of examining them. I am also indebted to my house physicians, Drs. Van Rensselaer and Huber, for valuable assistance in making and repeating the observations.

CASE I.—G. W——, aged forty, tongue amputated December 2, 1889. At first could taste little or nothing, but in a short time after the operation recognized sweets.

Careful examinations were begun in April, 1890, about four months subsequent to the operation. There was no anæsthesia to touch, heat, or cold in any part of the buccal or pharyngeal cavities. Precautions were of course taken to prevent the patients from knowing anything of the nature of the solutions used, and the parts were well rinsed after each application.

This patient was first given a mouthful of each of the following solutions to swallow: Sol. quiniæ sulph., 1 to 12, tasted bitter; syrup simplex, tasted sweet; sol. sodii chlor. (two per cent.), tasted salty; sol. acid tart. (five per cent.), did not recognize it.

Having determined that he recognized bitter, sweet, and saline qualities, but not acid, an attempt at localization was made by means of small cotton pledgets saturated with the sapid solution and applied to various areas on long silver probes. The results were as follows: A concentrated solution of quinine was feebly perceived as bitter on either side of the soft palate, but very strongly perceived when applied to the posterior wall of the pharynx.

Simple syrup produced no sensation on the soft palate, but presented its usual flavor when brought into contact with the posterior pharyngeal wall.

A concentrated solution of common salt was not perceived by the soft palate or by any part of the pharynx, but gave a mild salty taste when taken by the teaspoonful and swallowed. This would appear to indicate the presence of gustatory papillæ on the surface of the epiglottis, which have been assumed to exist there by several authors, but there were difficulties in the way of any exact localization. Tartaric acid in strong solution caused no sensation of taste in the soft palate, uvula, palatine arches, or pharyngeal walls. He spoke of a slightly sweetish sensation when the acid touched the posterior pharyngeal wall. In drinking lemonade the sweetness is perceived, but there is absolute failure of the sensation of sourness. Whiskey, swallowed in quantities, formerly delectable, produced a burning sensation, but had neither taste nor smell. He distinguished beer from whiskey by a mildly bitter taste of the former.

The galvanic current was then employed. At first sponge electrodes were placed on either side of the neck and a number of voltaic alternations given with ten Grenet cells. No taste was produced in the patient, although in myself a very lively and diffuse gustatory sensation was caused. Then a long double electrode of wire, in the form of a probang, the poles being isolated and one centimetre apart, was used to touch various portions of the buccal cavity, floor of the mouth, palatine arches, soft palate, and pharyngeal walls. A current from ten Grenet cells elicited a strong galvanic taste in myself, but the patient perceived nothing but a sensation of coldness imparted by the wire ends.

These experiments were repeated a number of times on different days and always with the same result.

A singular and almost inexplicable phenomenon in this case was the complete abolition of the sense of smell which followed the operation. Previously his olfactory sense had been perfect, but although months have now elapsed since the amputation of the tongue, the anosmia remains absolute. Such substances as iodoform, sulphuric and nitrous ethers, glyceritum fellis bovis, ergot, tar, sweet oil, oil of wintergreen, and valerianate of ammonia have to him no odor whatever, but aqua ammoniæ is readily recognized by its stimulation of the fifth nerve. It would be easy to understand how the perception of *flavor*, which is a quality compounded of both taste and smell, might be eradicated by the destruction of the taste component, but explanation of his entire loss of the olfactory sense is somewhat difficult. We must remember, however, that the sense of smell is the most easily disturbed of all of the special senses, very slight over-stimulation sometimes sufficing to destroy it; and it is possible that the long ether-inhalation or the later generous use of iodoform in such close proximity may have produced the anosmia in this case.

CASE II.—P. K——, aged fifty, was examined two or three weeks after a total extirpation of the tongue. He said he could taste some of his food slightly "down in his throat." On swallowing simple syrup he spoke of a sharp, bitter taste. A concentrated solution of common salt produced a feeble salty taste. A solution of quinine caused a sensation of sharpness and bitterness. Acid solutions could not be tasted. This man had no disturbance of the olfactory sense except as regarded flavors.

Conclusions.—The perception of sourness was lost altogether in both of these cases after extirpation of the tongue.

[1] Studien och undersökuingar öfver smaksinnet. Af Hjalmar Oehrwall. Ups. Läk. Förhandl, Bd. xxiv., Nos. 6-7, 1889.

In Case I. bitterness was feebly perceived by the soft palate, strongly by the posterior wall of the pharynx; sweetness was not perceived at all except on the posterior wall of the pharynx; saltness was not perceived at all by either palate or pharynx, but probably by the surface of the epiglottis; the galvanic current produced no sensation of taste whatever.

Case II. was examined so soon after the operation that much cannot be determined with reference to the amount of permanent disturbance of taste. Besides the loss of sensibility to acids, he did not recognize sweets.

201 West Fifty-fourth Street.

ANOMALIES OF THE CORD.

By HARRIS FISHER, M.D.,

EASTMAN, GA.

Case I.—During the present year I was called to attend Mrs. A——, the mother of three living children, and in labor with her fourth. The parturition was uneventful, child large and thrifty, and breathed and cried in the usual order. In the middle of the cord, however, was a knot which I would fain describe, but must confess in the beginning that nothing in the way of medical reporting ever troubled me so much. It was a puzzle in its details, and still simple to contemplate as a whole. It resembled strikingly the rectangular arrangement so often seen in a white-oak chair-bottom, or as the same material is interwoven in basket work.

The arrangement may be closely imitated by plaiting the index- and the middle-fingers of the respective hands, as follows: Let the index-finger of the right hand pass under the index-finger of the left, and rest on the dorsum of the middle-finger of the left; at the same time let the middle finger of the right pass across the tip of the index-finger of the left and rest beneath the tip of the middle-finger of the left. While the rectilinear arrangement of the body of the knot can be closely imitated in this way, the attempt to reproduce it with a continuous rubber cord proved utterly futile. The points of super-imposition had a slightly worn or much-used look. As to the mode of the formation of these knots, there are two theories: that they are created by the movements of the child, and that they are developed in the shape in which they are found. In the simple knot the first theory might obtain. In the complicated, to which this one belongs, the conviction is instantaneous that it was so developed.

In Charpentier's "Obstetrics" we have an array of these departures from the normal that would seem ample to cover any instance likely to occur in the experience of the general practitioner.

He gives five distinct varieties, some of them shown at different stages of development, making in all eight illustrations, but none of them conforming in any considerable degree to my case. He classifies knots of the cord into simple and complicated, single and multiple.

Lusk gives only one plate in illustration of knotted cords, a multiple, and one of the same, Leyman's, given by Charpentier. Mine would be a variety of the multiple, *multiple rectangular*—why not?

Case II.—Within the same month I was called by a negro midwife to a prolific sister of her own color, who had just been delivered of a still-born child. The main intent of her sending was to have me examine the cord, and, as she hoped, vindicate her from being in any way responsible for the death of the child, for the mother declared the child was alive up to a period just before delivery. Appearances sustained her. There was every indication and appearance of a child well grown, at term.

The labor, as well as I could learn, was quite normal, and the mother was doing nicely. My attention to the cord was especially invoked, and I saw before me a rope of very slightly yellowish fat. Length usual. In the middle of its continuity there was an enlargement strikingly sausage-shaped, six inches in length, almost round, a little tapering to a blunt termination, and one inch in diameter. The twist of the cord, so often noticed, was entirely effaced. The corded feeling in the normal structure was scarcely apparent upon the firmest pressure.

Subsequent section and dissection revealed the fact of a complete fatty degeneration of all the parts that make up the cord, from its umbilical origin to its placental expansion, and inclusive of the same; for the fœtal side of the placenta had a thin but distinct layer identical with the tissue of the cord. The sausage-like aneurismal enlargement proved to be a very firm clot of brightish-looking blood, more suggestive of arterial than of venous origin, encased in the amniotic and chorionic layers of the cord.

Evidently, as the history of the case would seem to bear me out, some strain upon the fragile cord just before the birth of the child, ruptured one of the arteries and produced this apoplexy of the cord, cutting off the circulation. Upon a careful exploration of this long clot it was impossible to trace a vestige of any of the vessels. Upon a section of the fatted cord, on either side, the smallest bloody points indicated the severed vessels. Splitting the cord and spreading it out on a smooth surface, the slightest striated appearance indicated the track of the vessels in a tissue strikingly homogeneous.

The most interesting fact in this singular case was the conservatism of its pathology. It is something unique, in this sweeping metamorphosis, that it should have gone on so nearly to completion, involving the vessels alike, and still leaving them competent to carry on the circulation to the hour of birth; and, but for the timely assistance of a physician that was wanting, sufficient for the life of the child. There was every reason to believe that the use of the most ordinary means would have brought about resuscitation.

Of recent works on anomalies of the cord I have convenient for reference only Lusk and Charpentier. The former, Lusk, disposes of the whole subject of degeneration of the cord in two lines, merely announcing the fact of "calcareous degeneration." Charpentier gives us twelve pages on "The Cord," profusely illustrated. Speaks of rupture (severance) of the cord as a possibility in the third stage of labor, but makes no allusion to tissue degeneration and ruptured vessels.

In Pepper's "System of Medicine" there is a deep and instructive article by Reginald Fitz, M.D., on "Degenerations," fatty and others. In this he alludes incidentally to degenerations of various organs and tissues, but nowhere cites the umbilical cord.

I forbear to occupy further space upon a subject of no more practical importance, with the calling special attention to the fact that, notwithstanding the composition of the cord—arteries, veins, Wharton's jelly, and the amnio-chorionic envelopes, differing tissues and organs wound one upon the other—the degenerative invasion was complete, passing all boundaries. Further, that a diligent search in medical literature, current and old, is not likely to produce a similar case.

Iodoform Injections in the Treatment of Cold Abscess.—Dr. Jasinski, of Cracow, has treated eighty-six cases of cold abscess by means of injections through a trocar of iodoform emulsion, with encouraging results. A certain number were cured by a single injection, others after two or three injections. In eleven cases after the injection the abscess broke, a large quantity of pus mixed with iodoform being discharged. These were all cured without any further surgical interference. In nineteen cases an incision had to be made; the cavity was then washed out with carbolized water, iodoform emulsion injected, and the wound sewed up after a drainage-tube had been inserted. In some of these cases the injection had to be repeated several times. Though one hundred and eighty grammes of a ten per cent. emulsion were injected at once, no toxic symptoms were ever observed.—*Lancet.*

INTUBATION OF THE LARYNX IN DIPHTHERITIC CROUP.

By F. W. LESTER, M.D.,

RESIDENT PHYSICIAN, WILLARD PARKER HOSPITAL, NEW YORK.

THE success of any operation, we must admit, depends largely upon the subsequent management and treatment of the case, whether complications by sequence or accident present themselves or not. A fatal termination of an operation skilfully and brilliantly performed may be due to such causes; the value of the operation, however, will be determined by results rather than by possible methods of procedure.

Intubation has been practised, and it has become a recognized fact, and doubt no longer exists as to it being a life-saving agent, if not the best means at our command for fighting that formidable disease—diphtheritic croup, or membranous laryngitis.

In the hands of a skilful operator the operation is simplicity itself, and can be performed in an instant—a desideratum which commends it. Better results can be obtained in hospitals than in private practice, especially in one properly equipped for the operation, for the nurses in attendance, by reason of special training and long experience, acquire great skill in the after-management of the cases. It is exceedingly painful to observe an inexperienced doctor and nurse at the operation, the one unable to locate the larynx, and the other unconsciously letting the patient slide down off her lap, and after considerable digging and ploughing into the inflamed soft parts of the throat, the tube lets go and finds its way into the œsophagus, an appalling and embarrassing situation for all concerned, and thus it is that an unskilful attempt and absolute failure at the performance of any new operation engenders doubt and positive resistance in the minds of the laity, and adds additional momentum to that feeling of hostility toward a truly scientific and successful procedure.

The operation should never be attempted, except by an experienced operator. The introduction of the tube gives instant relief from the stenosis, except in rare instances where the case is hopeless by reason of excessive membranous deposit and purulent exudation below the bifurcation of the trachea, and in such an exigency all other resources are inexpedient, for tracheotomy in this event would avail nothing more. Yet in no case, no matter how desperate and hopeless it may seem, do I hesitate to do an intubation, for I recall one successful case in my experience where a rapid exfoliation of membrane occurred upon the insertion of the tube, the tube itself assisting in the dislodgement of the membrane, but further occluding the trachea by pushing it downward, and rendering obstruction complete for an instant, but which the immediate withdrawal of the tube relieved by removing with it a perfect cast of the trachea and a considerable portion of the right and left bronchi. Not a single death has occurred in any of my cases during the operation.

In some cases it will be found that the calibre of the tube is too small to permit of very large pieces of detached membrane being discharged through it by any effort the patient may make at coughing; but for this emergency we have at our command Dr. O'Dwyer's large-calibre tube, designed for temporary use only, and through which the membrane finds a ready exit if the patient is able to expel it. This tube is somewhat more difficult to introduce, and may do harm to the larynx if not properly inserted before the obturator is withdrawn, for it has quite a sharp extremity. While intubation has furnished us with a valuable alternative in the treatment of diphtheritic croup the operation should never be performed until all other measures fail and the stenosis urgently demands it. I have observed several recoveries in this hospital which have occurred without operative interference, though the patient's condition at times seemed grave enough to warrant operation; the apparent extreme obstruction was transitory only, and was relieved by emetics and other treatment. Much depends on the management of the case, which, from the start, requires increasing vigilance lest temporary obstruction, due to loose membrane in the trachea and tube, cause asphyxia and death, which may be averted by opportune administration of emetics and the removal of the tube temporarily, or by substituting the large-calibre tube.

The presence of membrane on the tonsils, posterior nares, and pharynx, and enlargement of the cervical lymphatics, amounting sometimes to great puffiness of the whole neck, presents a fatal aspect to the case when those lesions are excessive, for in such cases we will most likely have nephritis, sepsis, exhaustion, and sudden heart failure due directly to the long continuance of the disease and its specific poison.

On the other hand, in those cases in which the above lesions are present to only a moderate degree the prognosis is rather more favorable than when laryngeal diphtheria occurs as a primary disease and is unattended by an invasion of other parts of the throat and nasal passages, for, as is usually the case, the exudate forms rapidly and copiously, distributing membrane which obstructs the larynx and trachea at very short notice; and from this fact it will appear that a condition is present at the seat of disease favoring active growth of the morbific element; hence the march of the disease is too rapid to be arrested by means at present at our disposal.

I have purposely omitted arranging a table according to the duration of the laryngeal symptoms before operation became imperative, as it was found impossible to obtain reliable data bearing on this all-important point in every case, owing to the inability of mothers to speak English, and in some instances nobody seemed to be responsible for a history. So the stand I take is based on the cases which actually came under my own observation.

The question of treatment is an all important one, both general and specific. For the latter the plan laid down by Professor A. Jacobi, namely, iron and potash mixture in small doses every half-hour, and the bichloride of mercury (gr. $\frac{1}{4}\frac{1}{0}$ to $\frac{1}{8}\frac{1}{0}$ every hour) has been adhered to, and excellent results have been attained by this course of medication, as the statistics below will show. For general treatment we can not look to any routine plan, as every case should be treated on general principles. For instance, high fever should be reduced by sponging and bathing, weak heart and collapse promptly treated by stimulants and heart tonics, and urgent reflex symptoms, as vomiting, checked if possible. A liberal use of stimulants and nourishment must be maintained throughout the disease, for we are dealing with a poison which may become septic in character. There is danger of giving too little stimulants rather than too much; in the septic form I have given a child, five years of age, eight ounces of whiskey in twenty-four hours without inducing alcoholic intoxication. Nephritis, when it is present, should always engage the solicitude of the physician and be speedily met by appropriate treatment. Pneumonia is also a dangerous complication, but it does not recur often.

For the first six months of 1889 twenty-three operations were performed, of which 9—or thirty-nine per cent.—recovered. Males, 14; females, 9. Average age, three years five months. Average age of those that died, two years eleven months; of those that recovered, four years two months. Albumin was present in the urine in 10 cases, not present in 1 case, and specimens could not be obtained in 12 cases. In fatal cases the average duration of life after intubation was four days. In cases of recovery the average time of tube in the larynx was six days eleven hours.

For the second six months of 1889 seventeen operations were performed, of which 8—or forty-seven per cent.—recovered. Males, 13; females, 4. Average age, three years eleven and one-half months. Average age of those that died, two years nine months; of those that re-

covered, five years four months. Albumin was present in the urine in 7 cases, not present in 1 case, and specimens could not be obtained in 9 cases. In fatal cases the average duration of life after intubation was three days sixteen hours. In cases of recovery the average time of tube in the larynx was five days twenty one hours.

For the first six months of 1890 18 operations were performed, of which 7—or thirty-nine per cent.—recovered. Males 10; females 8. Average age, two years seven months. Average age of those that died, two years; of those that recovered, three years five months. Albumin was present in the urine in 3 cases, and specimens could not be obtained in 15 cases. In fatal cases the average duration of life after intubation was two days thirteen hours. In cases of recovery the average time of tube in the larynx was six days ten hours.

Clinical Department.

A CASE OF HEMI-GLOSSITIS PHLEGMONOSA.

BY CHARLES H. KNIGHT, M.D.,

NEW YORK.

THIS seems to have been a case of what has been called by Craigie "lingual quinsy," in other words, an acute inflammation involving the base of the tongue as well as the tonsil. The patient was a boy, fourteen years of age, evidently very poor, who came to my clinic at the Post-Graduate Medical School, June 14, 1890. He could hardly speak intelligibly, but we were able to learn that he had had "sore throat," gradually getting worse, for four days. He felt chilly, but had had no well-marked chill. Odynphagia prevented him from eating, even the attempt to swallow fluids being very painful. Salivation was extreme. The gums were red, swollen, and sensitive, inclined to bleed, and along their dental margin there was a line of adherent secretion, almost like pseudo membrane. The jaws could barely be closed without biting the tongue, the border of which was deeply indented and eroded. The tongue was absolutely fixed; it could not be protruded nor could its tip be raised. Its dorsum was covered by a thick "fur." The odor of the breath was almost intolerable. Buccal temperature was 101° F. The left half of the tongue was not affected. The right side was much thickened, was very hard and resistant, and on passing the finger well back to the base a point of extreme sensitiveness was found. Fluctuation could not be detected. It was difficult to explore the oropharynx, but both tonsils were seen to be large and inflamed, and the whole faucial region was very red; but there was no indication of abscess.

Another striking feature of the case was the extraordinary submental swelling. The tissues from the point of the chin to the hyoid were tense, brawny, very sensitive, and swollen. In the expectation that the tongue might need to be scarified, I sent the boy to the Manhattan Eye and Ear Hospital, ordered a calomel purge, the external application of ice-bags, and the use of a cold carbolized mouth-wash. The next day the symptoms were somewhat worse, and I substituted, for the cold treatment, hot flaxseed poultices and frequent irrigation of the mouth with hot water. In my visit the following afternoon, I found that the abscess had ruptured during the morning. It was impossible to estimate the quantity of pus discharged, but it was sufficient to saturate the pillow on which the patient lay. All the symptoms were almost immediately relieved. The swelling beneath the jaw had disappeared; the tongue was still sensitive and stiff, but to a much less degree. The patient could speak more distinctly, and was anxious to try to eat something. From this time he steadily improved, and on the seventh day he left the hospital.

The point of rupture of this abscess could not be exactly determined, in this respect differing from a similar case reported by myself five years ago (MEDICAL RECORD, July 25, 1885). In the latter case the opening was found and a bent probe could be made to enter the abscess cavity.

The etiology of this, as of many kindred cases, is more or less obscure. There is no history of traumatism or of special exposure. The development of the lesion was doubtless encouraged by privation and poor food.

Progress of Medical Science.

Significance of Difference between Two Radial Pulses.—One by one erroneous notions are corrected by more careful observation. From the time of Marey, whose name is inseparably connected with the sphygmograph, it has been the common belief that a difference between the two radial pulses in the same patient is highly significant of aneurism of the aorta, or of one of the great vessels coming off from it. It is true that in some cases of aneurism of these vessels the pulse in the affected side is felt to be retarded, and to differ in volume and in tension from that of the healthy side. The sphygmograph records much more accurately the condition; it shows a low, sloping up-stroke, a rounding of the summit, and a more gradual descent than in the pulse of the unaffected side, the tracing being wave-like. But it appears that this condition of the pulse, and the sphygmograph, which has been regarded as characteristic of aneurism, is not due to aneurism *per se*, that it may be present in the absence of aneurism, and may not be present when aneurism exists. According to Ziemssen, it is the result of a narrowing of the artery—innominate or subclavian, as the case may be—and while it may occur in aneurism, as the result of pressure, for example, it is most frequently the result of arteritis deformans, an atheromatous condition

of arteries which frequently results in narrowing of the vessel. Ziemssen gives brief notes of eight cases; in four of them the pulse-tracing which has been believed to be characteristic of aneurism was present, but there was no aneurism, the lesion, as proved by autopsy, consisting of a narrowing of the mouth of the subclavian artery as the result of arterio-sclerosis. In the remaining four cases, the pulse-tracing of the two radials showed no essential differences, but there were manifest physical signs of aneurism of the arch, such as pulsating tumor, paralysis of the recurrent laryngeal nerve, etc.; in one of these cases the diagnosis was established by autopsy. The fact that stenosis of the great vessels may produce the difference in the pulses in question has not altogether escaped observation by other writers. Quincke hints at it, and Broadbent reports a case in which the lesion was actually discovered post-mortem; but he speaks of it as a "remarkable case." Arterio-sclerosis of the aorta is much more common than aneurism of the arch; it should, therefore, be very easy to confirm the statements of Ziemssen. The subject is of importance in prognosis as well as in diagnosis, and we hope it will receive attention on this side of the water.—*Medical and Surgical Reporter*, July 19, 1890.

Panbotano as a Substitute for Quinine.—Panbotano, of the family of leguminose mimosæ, is a tree indigenous to Mexico. Although it contains neither alkaloid nor glucoside, an alcoholic extract has been employed by Dr. Valude in the treatment of malarial fevers. The preparation which the author employed was made by macerating 70 parts by weight of the crushed bark in 1,000 parts of water which was boiled down to one-half the volume. Of this one pint might be taken in twenty-four hours by the patient. Dr. Valude has published notes of fifteen cases in which this remedy had been administered, of whom eight were affected with intermittent fever, and which are the only ones of interest in this connection. It is claimed that in 88 cases a single dose, or in some cases two doses, were sufficient to prevent the febrile access. The remedy is stated to be tolerably well borne, although in some cases a certain amount of vomiting is stated to be produced. These unfavorable effects, however, were avoided when the medicine was given on an empty stomach. These clinical results admit of no physiological explanation, and the absence of an alkaloid in the plant, and the small number of cases reported by the author, go far to detract from the reliability of the results which were claimed to follow its administration. For a long time numerous substances have been proposed as a substitute for quinine, but as yet no one substance has succeeded in filling the bill. As to whether panbotano will prove more successful than other substances remains yet to be seen, though we must confess that we possess considerable scepticism in the matter.—*The Therapeutic Gazette.*

Cancer of the Rectum and Pregnancy.—Dr. Löhlein, of Giessen, having under his care a case of this kind, induced premature labor eight weeks before term. A fort night later, the rectum was successfully excised. The author also discussed the merits of the line of treatment which was pursued in this case. He maintained that waiting was wrong in any case of cancer. Operations on a pelvic organ during pregnancy entailed unusual danger from hemorrhage, difficult to check under the circumstances. Abortion—a very probable result—would disturb the operation wound. Therefore he held that when rectal cancer was diagnosed in a pregnant woman, labor should be induced, and an operation performed on the rectum as soon as possible. A serious accident occurred in connection with the case above mentioned. It caused a puerperal epidemic, whereby two newborn children died of erysipelas and a lying-in patient had severe fever which fortunately did not prove fatal. This accident proved that, in lying-in hospitals, there may be other sources of infection besides the discharges, excreta, and exhalations of parturient women. New growths, beginning to break down, may escape the vigilance of trained midwives.—*The British Medical Journal.*

Salicylate of Sodium in Cholelithiasis and Pleurisy.—Professor Stiller, of Buda-Pesth, has used salicylate of sodium as a cholagogue for five years, and has found it better than any other drug in rapidity and certainty of effect (*The British Medical Journal*). He gives the following illustrative case, which is one out of many: A man, aged fifty, had suffered for about four months almost daily from severe bilious colic, and had been jaundiced for about three months. Rigors, with a high temperature frequently occurred. He was so emaciated that his appearance suggested cancerous cachexia. The liver was enlarged and resistant, but smooth. The gall-bladder could not be felt. After a week's treatment with salicylate of sodium the pains and fever disappeared, the icteric color decreased, vomiting ceased, and after a four weeks' stay in the hospital he was dismissed cured. The details of the mode of treatment are as follows: Half a gramme of the salicylate was given four times a day. It was given in half a glass of soda water, or any other alkaline water—never in wafers, as these increased the gastric irritation. Usually 0.01 gramme of the extract of belladonna was added to each dose, as a non-constipating anodyne. Linseed poultices were applied over the liver. The patient was kept on moderate diet for several days, and alkaline water, free from iron, was given as beverage. Occasional pains were relieved by injections of morphine. Carlsbad and Vichy water was ordered by way of after-treatment. The cholagogue properties of the drug had also been proved by experiments on animals. In cases of pleurisy, Professor Stiller has noted a very striking diminution of the effusion when salicylate of sodium was given. Absorption occurred in a surprisingly rapid way, and Dr. Stiller recommended the drug, even for diagnostic purposes, as excluding the purulent character of the exudation. From three to four grammes in solution were administered daily, a spoonful being given every hour or two hours. The primary effect, no doubt, was on the kidney, and the increased secretion of urine favored absorption. It was only recently that he had observed, that the quantity of urine was increased from 650 to 2,000 and even 2,300 c.c. under the influence of salicylate of sodium. The drug was also useful in sciatica.

Prophylaxis of Impotence in Olden Times.—A favorite method of revenge practised by a discarded lover, in ancient times in France, was to conjure impotence upon his successful rival. All that was necessary was to take a linen thread or a skein of flax and knot it in a peculiar way known to those who cultivated the black arts, singing at the same time a curse upon the victim. The latter would then find himself in a sad predicament, powerless to consummate the marriage which he had entered into. But the remedy was always at hand, for the bride and groom had but to repair to the priest and kneel before him side by side in such a way that the hip, knee, and elbow of the one pressed so closely against the same parts of the other that the finger could not be insinuated between them. This was useful as a remedy, but the husband might avert the calamity entirely and dissolve the spell if he had reason to fear that it had been imposed upon him. The way to do this was simply to urinate through the wedding-ring, which had, of course, been blessed during the marriage ceremony.

The Doctors Have Themselves to Blame.—Philadelphia is said to contain about one million people, more comfortably cared for than the people of any other city. Yet it is also said that two hundred and fourteen thousand of these receive pauper medical services. This is exclusive of private dispensaries, or the multitude treated by doctors free in their private practice. All this is due to the fact that doctors have taught the people that they desire to work for nothing.—*American Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, August 30, 1890.

RUNNING TO EXTREMES.

Is it not about time to halt a while in our restless search after the microscopical accompaniments of certain diseases, and pause to consider what we are accomplishing, and whether there is not some danger of becoming men of one idea, narrow to the extreme in our conception of what disease actually is, and of how we ought to combat its ravages. It may be that we are no different from other men, yet it would seem as though medical men might be justly called the Athenians among men of science, in that they "employ themselves in nothing else, but either in telling or in hearing some new thing," and when they have found that new thing they let everything else go and cling to that alone. It is thus with the study of bacteriology. It has been ascertained almost to a certainty that the tubercular process, for example, is associated with a certain form of microscopic growth which is not found as an accompaniment of other diseases. It is therefore assumed, correctly no doubt, that this micro-parasite is the cause, either directly or indirectly, of tuberculosis. Other microbes have been found in relation with other diseases, and it has also been assumed that a causal nexus exists. This is well enough, it is a plausible theory, and one that offers great hope of advance in the therapy of certain diseases, and if it does not blind us to the actual necessities of treatment and lead us to neglect the plain indications while running after some specific microbicide, there is no objection to its further study and amplification. But here is where the tendency of mankind, in general, and seemingly of the medical profession, in particular, to ride a hobby to death betrays itself. Some are not satisfied in accepting what has already been proven, but they must assume what remains to be, and which possibly never will be proved. They look for the bacillus in every departure of the human organism from health, and they run a serious risk of making themselves, as well as the science which they study, ridiculous. Not long ago it was gravely announced in an Italian journal that some one had discovered the bacillus of old age. Of course that was intended as a joke, but so ready at the present day are some minds to see the infinitesimal in pathology that not all could see the joke, and several medical papers reproduced the item containing the announcement of the great discovery in all seriousness, never for a moment seeming to see in it anything but the most natural discovery, and one that would explain many of the lesions found in those of advancing years. But there are other things put forward in good faith which are almost as ridiculous. Not long since a Russian investigator examined the water obtained from melted hail-stones, and found it to contain several varieties of bacteria. There was nothing very remarkable in this discovery, for it would have been strange had no bacteria been found, but what was remarkable was the conclusion which the man drew. He thought it very probable, since rain, snow, and hail had all been found to contain micro-organisms, that there was a specific, and hitherto undescribed, disease to which only those were liable who had been exposed to a storm and had been wet to the skin by water containing these peculiar bacilli. It is not the search after microbes that is absurd, but the conclusions which many run to without first establishing their premises. We are not yet in position to assert that there can be no disease without its specific micro-organism, and those who do so maintain are in danger of making their science a subject of ridicule to men whose range of vision extends beyond the microscope field. They also interfere with therapeutic progress by turning men's minds away from the phenomena of diseased action and hunting after an invisible foe, which may after all be found to have less power for evil than it is now credited with.

THE RESPONSIBILITY OF THE PHYSICIAN FOR EXPERIMENTS UPON PATIENTS, EVEN WITH THE LATTER'S CONSENT.

A CASE was recently tried in a Cincinnati court in which the conditions were rather peculiar, and in which the finding of the judge was of interest to others than the one directly concerned in the matter. It seems that a physician of that city was sued by a man who claimed to have been injured by experiments with the elixir of youth. The man had been paralyzed for some time, and could get about only with much difficulty. The physician called him in as he was hobbling past his office, and proposed to try the effect of the "elixir" on his paralysis. The old man consented, and a charge of the stuff was injected into each leg. The result was that an abscess formed on his paralyzed leg, from which he suffered greatly.

The patient did not apply to the doctor for treatment, and the doctor made no charge for what he did. It was an experiment, attended with danger, which the doctor was eager to make, and the patient, with perhaps a limited understanding of the matter, seemed willing should be tried.

It was contended by the defence that the case was not one of malpractice, nor could it quite be called an assault, and it fell short of the definition of a tort. Although the sufferings of the patient might be directly traceable to the doctor's act, yet it was a question whether the doctor did anything of which the law could take cognizance.

The jury, however, brought in a verdict against the defendant, assessing the damages at seventy-five dollars. The judge charged the jury that it is not malpractice where a physician treats a patient upon his own motion and without pay, but the physician is bound to use ordinary skill even under such circumstances, and if he does not use such skill, or is guilty of carelessness, he is guilty of a tort for which he is liable in damages.

We are sorry for the physician who was obliged to pay damages, yet the decision seems to be a just one. It will serve, at any rate, as a useful warning to others not to experiment carelessly with any medical fad that may be proposed, before they know anything about its merits or its dangers.

FURUNCULOSIS AND POLYURIA.

The coincidence of diabetes mellitus and furunculosis is so often observed, that there are few now who doubt that there is some causal relation between the one and the other. In regard, however, to diabetes insipidus the belief has been less general; indeed, it has been denied by many that there was any liability to the occurrence of furuncles or carbuncles in the subjects of simple polyuria. Some recent writers, however, have stated as their belief that furunculosis is a frequent accompaniment of simple diabetes, and this view receives some confirmation from a case reported in the *Centralblatt für Klinische Medicin*, No. 21, 1890, by Dr. Lowinsky. The case was one of diabetes insipidus occurring in a workman, aged fifty-six. After he had suffered for some time from the ordinary symptoms of this affection, he began also to be troubled with numerous crops of boils which returned again and again in spite of the most varied treatment. There was no cause for this to be discovered, and traumatism was readily excluded. The author, in searching through the literature of the subject, found many similar cases in which furunculosis appeared without any apparent exciting cause in the subjects of diabetes insipidus, and he comes to the conclusion that there is here also some etiological relation which has as yet not been traced. but which nevertheless exists.

IGNORANCE AMONG ENGLISH MEDICAL MEN.

Some of our friends on the other side of the water have enjoyed themselves not a little during the past year or so in exchanging anecdotes about American physicians, whom one and another have met on their travels, and who were not perhaps noticeably erudite. Some of the tales related in the British journals may have been true, for we are well aware that there are practitioners of medicine in this country as well as in others who, sensible and practical physicians though they are, are yet not cultured. But it ill-becomes our English confrères to sneer at American physicians when they themselves are so vulnerable. The samples of British doctors that are sent over here in the capacity of ship surgeons for our inspection, are not all specimens to boast of. We referred not long since to the complaint of the Health Officer of the Port of New York, concerning the inefficiency and gross ignorance of many of the surgeons employed by the transatlantic steamship companies, and recently this fact was emphasized in Boston, when an English vessel brought over a leper from Liverpool. The woman had been allowed to enter England and then to board the steamer at Liverpool, the medical officers of the Board of Trade, as well as those of the steamship company, having had no suspicion apparently of the nature of the disease. It was reserved for ignorant Yankee doctors to detect the leprosy and to return the patient properly labelled to England. The health authorities in Glasgow have called attention to the fact that in nearly eight per cent. of the cases of supposed contagious disease sent to the fever hospital by the physicians of that city, there was a mistake in the diagnosis, and many of the patients were found actually to be suffering from no contagious disease at all. Really we think the display of a little modesty, not to say humility, by our English "cousins" would be not at all unbecoming.

MALARIAL INOCULATION AND THE INTRAVENOUS INJECTION OF QUININE.

Ever since Gerhardt first produced typical intermittent fever in the human being by the direct transfusion of a little blood taken from a malarial patient, similar observations have been from time to time recorded. Recently Dr. Gualdi, working under the supervision of Professor Bacelli, of Rome, has instituted a new series of investigations touching the subject of malarial inoculation. It was found that the blood of a malarial patient injected into the veins of a healthy subject invariably produced paludal infection. The quantity of blood used for each injection was small, and did not exceed sixteen minims. It was further ascertained that the incubation period did not vary, and lasted just twelve days.

An interesting circumstance was also noted in the fact that the precise type of the patient's disease was reproduced in the inoculated persons. That is to say, if blood was taken from a patient suffering from quotidian ague the inoculated subject would develop quotidian intermittent fever; if quartan, a quartan type would follow; a tertian fever always induced tertian ague, etc.

The blood of an inoculated person invariably showed the presence of the plasmodium described by Marchiafava and Celli, and what is more, the stage of evolution of the plasmodes corresponded to the type of the disease.

Dr. Gualdi asserts that the crescentic bodies known as Laveran's plasmodes, which have been repeatedly found in the red blood-corpuscles by different observers, represent but a late stage in the development of the Marchiafava and Celli organism. If this be true it would harmonize in a plausible manner the hitherto somewhat conflicting claims of these Italian authors. The parasitic nature of the plasmodes admits of no doubt, according to Gualdi.

Professor Bacelli has also instituted a number of therapeutical experiments. As might have been expected, the most convincing and satisfactory results were obtained with quinine. In pernicious malarial fevers, gastric and subcutaneous resorption are much interfered with. Accordingly quinine was injected directly into the veins. A prompt effect was seen. But as much as fifteen grains of the hydrochlorate of quinine were administered in this way before decided amelioration occurred. No unpleasant consequences were observed to follow this procedure. The formula employed by Dr. Bacelli was as follows:

Quin. hydrochloric	1.0 gramme.
Sod. chlorid	0.075 "
Aq. destillat	10.0 grammes.

He directs that the fluid is to be filtered, warmed, and injected into a vein of the forearm, under strict antiseptic precautions.

The success of this method of treatment is said to depend in large measure upon the time of injection. If the injection be given before the febrile attack has already begun, even fifteen grains will not suppress the paroxysm. So, too, when practised during the acme of the seizure defervescence is not hastened. The most suitable time is the period of natural subsidence of the febrile movement. Given at that time, the next anticipated attack is either entirely suppressed or considerably reduced in intensity.

In subcontinuous fever injections practised during defervescence are particularly efficacious.

But in spite of the good results thus obtained Dr. Bacelli is not an advocate of the indiscriminate application of the intravenous method. For, says he, in ordinary malaria thirty grains of quinine given by the mouth or injected subcutaneously, usually fulfil every indication. It is only when quinine is found inert if administered this way, and more particularly in the pernicious forms of fever, that he strongly urges the intravenous injection of the drug.

News of the Week.

Cholera is still spreading along the coasts of the Mediterranean. The London case is stated to have been merely an instance of cholera morbus. On the other hand, some decidedly suspicious cases have been reported near Berlin. In the South of France it is also quite likely that the disease has gained a foothold, although the local authorities have made strenuous denials. The near approach of cold weather will serve, however, to reassure timid people on this side of the Atlantic.

The Relative "Wages" of Physicians and Mechanics.—The Eastern Dispensary of New York pays its physicians for daily service $200 a year, or nearly 33 cents an hour. The Eastern Dispensary is a pioneer institution in medical generosity. This is good, but less than carpenter's wages. The appointments are made after competitive examinations, and are eagerly contested. There are many "contract doctors" who work for much less than this.

The Startling Excess of Medical Charity in Edinburgh.—Almost one-half of the people of Edinburgh, Scotland, receive their medical advice gratis. The *Scotsman* has published some authentic figures, which may or may not, but certainly should, afford food for reflection to those who have the best interests of the profession at heart. "The population of Edinburgh is little over 236,000, and that of these, 103,095 should be entirely dependent on charity for medical advice is evidence of a rather discreditable want of self-reliance and providence among the working classes. Nor is this all. The number of persons who in any year actually avail themselves of such aid must of necessity be smaller than the total number who would do so were they forced by sickness or accident, and it looks as if more than half the population were in the habit of expecting medical treatment gratis." In the city of New York wealthy hospital magnates are fast teaching the people the lesson that they have already learned in Edinburgh. The final outcome of this pernicious system is needlessly degrading to the populace, at the same time that it saps the strength of the profession. Such indiscriminate "assistance," instead of diminishing, will inevitably augment, pauperism. Only the paupers of the future will be the doctors, who are sure to be ground to death between the upper millstone of free advice for all classes, and the lower one of large fees for a few fashionable specialists. But "What are you going to do about it?"

Homœopathic Hospitals.—Michigan is not the only State that contributes money for the erection of homœopathic hospitals. Connecticut has lately contributed $30,000 for the erection of such in New Haven.

Perfectly Justifiable Charges.—Lawyers always charge for time consumed in the interest of their clients. Dentists charge for time. But when a mere doctor attempts to do so, the collector has a hard time of it. Here is a case in point, reported in the *London Daily News*. A case about doctors' fees has just been decided at the Liverpool Assizes. Dr. Day sued Mr. L——, a tenant farmer, for £365 6s. Mr. L——declared the charge excessive, and he paid £180 5s. into court. Here is an "item" in Dr. Day's bill: "Long conversation with Mrs. S—— on behalf of Mrs. L—— with regard to the use of some quack remedy which she recommended and I declined, 10s. 6d." Half a guinea for gossiping with Mrs. S—— about his patient, Mrs. L——! "You needn't have done it," observed cross-examining counsel, plaintively. There was also an entry of 7s. 6d. for "writing a letter to a specialist" about his patient, Mrs. L——. "Worse than an attorney; he would only charge 6s. 8d.," remarked Mr. Justice Smith, but restricted his consideration almost entirely to preliminary and scientific education. Referring to the recent action of the General Medical Council and to the regulations of the Conjoint Examining Board, Dr. Wade said he proposed to consider the subject only as regarded students who intended to take an ordinary diploma—not as it concerned the fortunate few who had leisure to protract their studies. With respect to the time at the disposal of a medical student, Dr. Wade said that he inferred that the General Medical Council did not intend him to pass the preliminary examination before he was [illegible] for it had lately been suggested that

Hudson County, to serve for two years; Dr. George W. Brown, Monmouth County, for three years; Dr. W. L. Newell, Salem County, for one year; Dr. Henry S. Wagner, Somerset County, for one year; and Dr. Hugh C. Hendry, Essex County, for one year. *Homœopaths:* Dr. A. Uebalacker, Morris County, to serve for three years; and Dr. A. H. Worthington, Mercer County, for one year. *Eclectic*: Dr. Eugene Tiesler, Essex County, to serve for one year. The Board will meet for organization on Tuesday, September 2d.

Effect of the Pasteur Institute in Paris.—In the first five months of 1888 there were two hundred and eighty applicants at M. Pasteur's laboratory from the department of the Seine alone, all of whom had been bitten by dogs either known to be rabid or suspected of being so. This number was but little short of the corresponding total for the whole year of 1887, which amounted to three hundred and six.

Did not Find Laveran's Corpuscles.—Dr. Bruno, the pathologist of Charity Hospital, New Orleans, has not had Osler's and Councilman's success in finding the hæmatozoön of Laveran in the blood of many cases of malarial fever that he has examined.

The General Practitioner and Learned Leisure.—Dr. Freer, in the course of some remarks on a practice extending over nearly forty years, says: The general practitioner in the small town or country lives all his adult professional life too far off a large active centre to participate to any great extent in the advantages to be met with there. Nothing can be more calculated to curb ambition and to dispel the illusions he may have fostered when fresh from the schools. He soon finds that the drudgery inherent to general practice, and which he cannot escape, renders impracticable calm scientific investigation and the patient ticketings necessary to accurate research. The mental stress that comes to him in grave cases from the fact that the patient is not merely a patient, but often one bound to him by the ties of close friendship and of a mutual understanding of each other's virtues, peculiarities, and weaknesses (we must not imagine that the doctor studies the patient, and that the patient does not take stock of the doctor); the trouble he is oft put to, to allay the natural or excessive anxiety of "the sisters and the cousins and the aunts" (often his own friends, too); the numberless details of practice which he has to attend to personally for want of someone in charge who has the least notion of nursing—these all tend to knock the scientific aspirations out of the isolated general practitioner, and mock his sighing after a learned leisure.—*The Birmingham Medical Review*, August, 1890.

Precautions against Consumption.—In a circular on Precautions against Consumption, published by the State Board of Health of Pennsylvania, the following advice is [illegible] some etiological relation which has as yet not been traced, but which nevertheless exists.

IGNORANCE AMONG ENGLISH MEDICAL MEN.

Some of our friends on the other side of the water have enjoyed themselves not a little during the past year or so in exchanging anecdotes about American physicians, whom one and another have met or [illegible]

Neurasthenia and Nasal Disease.—We commend the following, which are the concluding words of an editorial article in the *Journal of Laryngology and Rhinology*, to the prayerful consideration of the entire medical profession. "The causes of neurasthenia, obscure as they are, are not to be sought in some slightly abnormal condition of an organ such as the nose; and to imagine that local treatment of this, or indeed of any individual organ, is going to reward us with successful therapeutic results, is to subject ourselves to such failures as Dr. More Madden very honestly has recorded. Many women live only for the gynecologist, and though we would not for a moment impute such conduct to members of a noble profession, there is no doubt that gynecology, in some unscrupulous hands, has not been free from chicanery in a class of patients in whom the loss of nervous control, which is the essence of neurasthenia, has rendered them ready agents to such practices. It would be a thousand pities were rhinology to incur the same reproach. To remove a vital cause of irritation is right and proper, but to assert that the slight pathological abnormalities met with in many nasal organs, even when they are accompanied with nasal catarrhs, is in real proportion of neurasthenic individuals a potent cause of their troubles, is, we think, to take up an untenable position. Those who, in such cases, look only to intra-nasal surgical treatment, and fail to appreciate the necessity of getting behind these apparent symptoms, and treating the general nervous system as of primary importance, will be doomed in their specialistic narrowness to failure. To say that such treatment, even if it does no good, will do no harm, is not correct. Very great aggravation of the patient's sufferings may follow injudicious and meddlesome interference. It is in neurasthenic patients, of all others, that we should exercise the very greatest discrimination in recommending or carrying out surgical treatment."

A New Method of Producing Local Anæsthesia.—According to the *Moniteur Thérapeutique*, local anæsthesia can be readily induced by simply discharging the contents of two or three syphons of aërated water upon the part. The anæsthesia thus induced is said to last about five minutes.

The Peter-Paul Hospital, of St. Petersburg, has been given 50,000 rubles to erect barracks for the treatment of acute diseases.

The Riberi Prize.—The Turin Academy of Medicine, has proposed the following theme for the Riberi Prize of about $3,750: "Researches on the Nature and the Prophylaxis of One of Several Diseases of Man." Works may be sent printed or in manuscript; they may be in Italian, French, or Latin; and printed works must have appeared since 1886. The date limit is December 31, 1891.

English Death-rates.—Dr. C. R. Drysdale says that at present the average age at death among the nobility, gentry, and professional classes in England and Wales is fifty years; but among the artisan classes of Lambeth it only amounts to twenty-nine; and while the infantile death-rate among well-to-do classes is such that only eight children died in the first year of life out of one hundred born, as many as thirty per cent. succumbed at that age among the children of the poor in some districts of our large cities. The only cause of this enormous difference in the position of the rich and poor with respect to their chances of existence, lies in the fact that at the bottom of society wages are so low that food and other requisites of health are obtained with too great difficulty.

The French Society of Hygiene will award in 1891 a gold medal of 200 francs, also a silver medal, and two bronze medals, to the authors of the best essays on the following subject: "What is to be done, before the arrival of the doctor, in case of a street accident, or accident in a factory." Further information, 30 Rue du Dragon, Paris.

The Consumption of Salt.—According to some statistics recently published in France, the annual consumption of salt per head in England exceeds that of any other country in Europe. For while in France the amount is estimated at about 30 pounds, Italy 20, Russia 18, Austria 16, Prussia 14, Spain 12, Switzerland 8, the Englishman requires no less than 40 pounds. The *Hospital Gazette* thinks that perhaps this is the secret of British thirst. If so, it offers an easy solution to the drink question, which the temperance party should not be slow in adopting.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Fifty-eighth Annual Meeting, held at Birmingham, England, July 29, 30, 31, and August 1, 1890.

(From our Special Correspondent.)

THE Fifty-eighth Annual Meeting of the Association was held at Birmingham, commencing July 29th.

At the morning session on Tuesday, July 29th, the chair was first taken by the retiring President, MR. C. G. WHEELHOUSE, of Leeds, only, however, for the purpose of vacating it in favor of the new President, DR. W. F. WADE, of Birmingham.

After the usual vote of thanks to the retiring President had been carried, the adoption of the Annual Report of the Council was moved by the President of the Council, DR. BRIDGWATER, and that of the Balance-Sheet by the retiring Treasurer, DR. HOLMAN.

The Association Prospering.—The Report referred to the satisfactory progress which had been made during the year. There were now more than thirteen thousand members of the Association. The finances were in a sound condition. The revenue amounted to thirty thousand pounds, being nearly four thousand pounds (twenty thousand dollars) in excess of the expenditure. The assets were in excess of the liabilities by a sum equal to one hundred and ninety-four thousand dollars. After some criticisms from Mr. Brown, which were replied to by Mr. Ernest Hart (the editor of the *British Medical Journal*), the Report and Balance-Sheet were adopted. Mr. H. T. Butlin was then elected as Treasurer for the ensuing three years in succession to Dr. Holman. The meeting then proceeded to the consideration of the reports of the various committees.

On the Adoption of the Report of the Parliamentary Bills Committee being moved by the chairman of the committee, MR. ERNEST HART, and seconded by SIR WALTER FOSTER, M.P., a somewhat acrimonious discussion took place, though happily it was not prolonged.

DR. RENTOUL proposed an amendment to the effect that as the Midwives Regulation Bill had not been adequately discussed by the profession, legislation on the subject should be delayed. He pointed out some of the objectionable features of the present bill.

MR. ERNEST HART, in opposing the motion, said Dr. Rentoul represented no one but himself, though he was fond of misrepresenting himself as having a mandate.

The chairman of the meeting ruled the amendment to be out of order, but suggested that it might follow as a substantive resolution. The Report of the Parliamentary Bills Committee was then adopted. Dr. Rentoul's motion was then carried, in spite of renewed opposition from Mr. Hart, who said Dr. Rentoul had no right to spring such a "rigmarole" resolution on the meeting. Several members referred with disapproval to Mr. Hart's tone.

The Honor of the Physician.—In the afternoon a sermon was preached to the members of the Association in St. Martin's Church by the ARCHBISHOP OF CANTERBURY, who took for his subject "The Honor of the Physician." The three great professions, he said, occupied the three chief fields of practical thought. They were: The self-revelation of God to man—religion; the equitable relations of man to man—jurisprudence; and the mystery of the life of man itself—medicine. Those fields were worked ever more exactly as critical philosophy, social science, and physiology reaped their several harvests of truth, and gave to age after age of man a slowly-advancing insight into the material laws, the spiritual laws, and the character of Him whom no man hath seen or can see. Little by little the conviction grew that what we saw without us and felt within us of imperfection, of loss, of decay, was not—could not be—final. We grew more, not less, able to understand that at last "this corruption must put on incorruption, and this mortal must put on immortality." The question, then, "What is the honor of the physician?" was not limited to him as a principal inhabitant of a city, a revered authority in a hospital, the glory of a college, or a man of European fame. It demanded what were his vocation and ministry in the Divine polity of the world? Inadequately the answer must be given, but no author had given us a key which turned so true in the intricate wards with which nature and existence were locked as that eighth chapter of St. Paul's Roman letter. The physician's field was, St. Paul would say, broadly, pain—the banishment of pain in the largest sense, very commonly the removal of pain by pain. There were strange analogies there, as, specially, the development of the causes of pain. St. Paul taught that all pain was fruitful, that in all pain there was a travail pain, that the manifold agony of Nature was the birth-throes of an exisient, imprisoned, struggling, already emergent life, far greater than the life we yet lived. An inkling of what St. Paul's words contained marked the office of a physician in its true relation to the world. Francis Bacon spoke of *Homo, Naturæ minister et interpres*; and part of that interpreter's vast function was performed by the physician. The preacher went on to consider the physician as exemplifying the law of kindness, the law of purity, and the law of reverence. With regard to reverence, he denied that the spirit of research interfered with it; reverence was rather starved without research than expelled by research of the most intimate kind. He quoted from Sir Thomas Browne, who thought our ordinary way of gazing upon some of the beautiful aspects of nature was a rude thing compared with the reverence of a physical scientist before that glory of God which he was slowly revealing.

Medical Education.—In the evening the members reassembled to hear DR. WADE deliver his presidential address. He chose for his subject "Medical Education," but restricted his consideration almost entirely to preliminary and scientific education. Referring to the recent action of the General Medical Council and to the regulations of the Conjoint Examining Board, Dr. Wade said he proposed to consider the subject only as regarded students who intended to take an ordinary diploma—not as it concerned the fortunate few who had leisure to protract their studies. With respect to the time at the disposal of a medical student, Dr. Wade said that he inferred that the General Medical Council did not intend him to pass the preliminary examination before he was seventeen years old, for it had lately been suggested that the professional curriculum should be extended from four to five years, and that, therefore, the earliest age at which a diploma should be granted must be raised from twenty-one to twenty-two. He therefore concluded that the Council proposed to allot seventeen years to preliminary education, one year to general science, three years to special medical science, one year to practical or clinical work. This brought the qualifying age to twenty-two. Suppose, for the sake of argument, we looked at the question from another point of view, and said that twenty-one should still be the age of qualification, and then worked backward, making at the same time a different allotment, viz.: one year practical or clinical work, three years special medical science, two years general science. By this arrangement general education would cease and scientific education would begin at the age of fifteen years. We saw here the germs of three important questions: 1. Should a diploma be obtainable at the age of twenty-one? 2. Should two years be compulsory in the study of general science? 3. Should compulsory general education be terminable at the age of fifteen? These three questions had, by implication, though not all categorically stated, been under the consideration of the Council at their last session; and they had all, in effect, been answered in the negative. Dr. Wade said he intended to submit reasons for suspecting that it was not, after all, quite certain that they should not all three be answered

in the affirmative. He then proceeded to discuss the points at issue. He urged that to raise the age at which a qualification was obtainable placed an undue pecuniary strain on poorer students. He maintained that two years was not too long a period to devote to science if scientific education was to be given. At present, early compulsory scientific instruction barely existed; compulsory scientific education did not exist at all. Instruction became education in direct proportion to the time spent in conveying it. The twelvemonth now to be allotted to science might serve to cram in a fair share of instruction in facts and phenomena, but it would be impossible to do more. It would be impossible to really enable one to grasp the great principles underlying these sciences. Even of the knowledge acquired, how much would cling? In two years a good deal might be done to remedy this. It was not too much, but could not be allotted unless compulsory preliminary education ceased earlier. Why should it not cease at fifteen years of age? He had lately obtained some particulars respecting the average acquirements of boys of thirteen at an ordinary Board School and had ascertained that they could pass about half the preliminary examination. Taking then the age of entry into the profession as seventeen, these boys would have about four years in which to acquire the balance of knowledge required. If we allotted two years to this—excluding Latin, which was not taught in Board Schools—we had two years to devote to Latin, and he considered this was sufficient to acquire the amount of Latin required. It was, of course, an obvious comment that these boys were never likely to seek admission into the profession.

From details of education given above, however, Dr. Wade drew the inference that, if Latin were excluded, the preliminary education might be passed at fifteen. What were the uses to which a medical man did actually put his knowledge of Latinity? (1) He wrote in his prescriptions the Latin names of drugs. (2) He wrote in Latin his instructions to the dispenser; (3) He wrote in Latin his instructions to the patient. It must also be allowed that he could, if so disposed, read easy passages from Celsus. The necessity for doing the three former things was of a purely arbitrary and artificial character; it had already crumbled and continued to crumble. As to writing the names of drugs in Latin: The Latin names were given in the Pharmacopœia, but the English ones were given, too. In the Addenda to the Pharmacopœia, only the English names were, he believed, given. In the synopsis of the Conjoint Board all the drugs were called by their English names only. As to writing in Latin our instructions to the dispenser: All directions to the compounder were, in the Pharmacopœia, written in English. As to writing the directions to patients: It was common knowledge that a large and increasing number of practitioners invariably wrote these in English, and it was equally certain that those who did so were as often to be found in the higher grades of the profession as in any other. There remained the question of the educational value of Latin. Was there any other system of which the educational value was equal, and of which the instructional value was superior? How far was it suitable for the class of minds upon which it was intended to impose it. The first question he had already dealt with. On the second question he preferred to quote the words of one (Mr. Gladstone) whom no one would accuse of indifference to classical acquirements. They were these: "In my opinion, classical education is in itself the very best of all for those who have a certain tendency toward it, and those whose circumstances are such as will enable them not to be content with the merest rudiments, but who will proceed to the point at which they will realize some solid attainments. Terrible errors have undoubtedly been committed in the past—and in the past I include the days of my own experience—in endeavoring to thrust the classics down the throats of everybody of a certain rank, quite irrespective of capacity and circumstance. I always bear this in mind, that the main purpose of education is to make the human mind a supple, effective, strong, available instrument for whatever purposes it may be required to be applied to." On this Dr. Wade said he proposed three questions: Did the Latinity exacted from every medical student answer best to the description of "merest rudiments," or of "solid attainments?" As regarded medical students, were "the terrible errors of the past," errors of the past only? Could the mind of a medical student be made as supple, effective, strong, and available an instrument for his purposes—so far as nature had endowed him with faculties—by no education unless it included Latin? Latin certainly stood in the way. Should it not, then, be placed in the list of optional subjects? He concluded by remarking that the danger now was that instruction might crowd out education; for indeed it was possible—"propter scientiam sciendi perdere causas."

A vote of thanks to the President was proposed by Mr. Jonathan Hutchinson, seconded by Dr. W. T. Gairdner, and carried by acclamation.

Proxy Voting.—The meeting was then made special for the purpose of considering a resolution on the subject of proxy voting which was brought forward by Dr. Hugh Woods. After some discussion the resolution was thrown out by a large majority.

Address on Medicine.—On Wednesday the second general meeting was held, when the "Address on Medicine" was delivered by Sir Walter Foster, M.D., M.P. He commenced his address with the remark that when he first came to Birmingham, some thirty years ago, it was beginning to go hard with the metaphysical battle-cries of the old school of medicine in the struggle then taking place between the old principle of authority and the modern principle of doubt. It was a veritable revolution and with it came a natural reaction against the empiricism of the older time, which resulted in a nineteenth century revival of the Hippocratic school. The study of the natural history of disease was once more exalted to the highest place, and the function of therapeutics lowered to the so-called "expectant method." Fortunately, this modern revival of what had been called of old a mere meditation upon death had in its extreme form but a short success. There was not enough inspiration in a gospel that taught its disciples that a warm bed was the treatment for pneumonia, and blankets and mint-water that for acute rheumatism. The cynical confession by these modern Hippocratists of their impotence to grapple with, and cut short, developed disease roused the impatience with which disciples of the aggressive school had always refused the passive function of mere observation. The external forms of diseases and the laws which regulated their courses were already well, if not perfectly, known, and so students were stirred more and more in the face of teachings of therapeutic powerlessness to search with renewed energy into the causes of disease. The study of medicine became more and more that of experimental pathology—not the morbid anatomy which generated despair by its revelations of the ravages of unchecked disease, but that modern pathology which, armed with instruments of precision and methods of delicacy, sought out the beginnings of disease and discovered new possibilities of final triumph. Thus, side by side with the teachings of Gull and his followers, grew the new school of experimental medicine. The time, too, was propitious. The physical sciences had reached a stage of their growth when medicine could borrow their methods, and—relying no longer solely on observation—could apply experiment and comparison to the solution of her problems.

The great Harveian principle, to search out and study the secrets of nature by way of experiment, was to bear fruit. In 1865, Villemin startled the world by showing the inoculability of tubercle, and Sanderson confirmed his experiments. The work had gone on ever since, till now, thanks to the labors of Koch, we could identify and isolate the bacillus of tubercle. The evidence had become

complete enough to satisfy most of the sceptics that a tubercle was not merely a neoplasm of definite histological structure, but a neoplasm containing within it a specific bacillus. It would be difficult to exaggerate the value of this great conquest of experiment, which was dissipating day by day the mystery that had through the ages surrounded consumption. Long before this we had, in seeking an explanation of many infectious maladies, assumed that some sort of fermentative process went on in the system, and so we called them zymotic diseases. When the labors of Schwann demonstrated that the act of fermentation was intimately connected with the multiplication of living yeast-cells and the result of their life a beginning was made for the germ theory of disease. The next step was the study of putrefactive processes and their intimate association with micro-organisms distributed in air, earth, and water. The doctrine of a living contagium as the cause of each specific disease received fresh support, and the vitalistic theory of fermentation, elaborately supported by Pasteur, led to the greatest of modern surgical triumphs in the treatment of wounds—a triumph which had immortalized the name of Joseph Lister. The fermentative and putrefactive processes were, under the growing sense of their importance, investigated with wonderful patience and remarkable skill alike by those who held the vitalistic theory of their causation and those who defended chemical views. By the experiments of Naegeli the great chemical champion (Liebig) was ultimately dislodged from a series of positions which he had defended with the greatest skill, and it was generally accepted that the presence of micro-organisms was essential to fermentation and putrefaction.

Nearly fifty years before, the writings of Henle had foreshadowed the connection of infective diseases with micro-organisms, and, in 1849, Dr. William Budd, of Bristol, had declared his belief that cholera and typhoid fever depended on living organisms. He, like many an ardent student, longed for and foresaw the day when, in connection with zymotic diseases, the initial phenomenon of the morbid series would be isolated and defined, as had been done in the case of parasitic diseases like tinea or scabies. That day was now at hand. The discovery of the bacillus of anthrax by Pollender, and the subsequent elucidation of its life and history by Davaine, Pasteur, Koch, and others, who proved it to be the actual cause of the malady, opened a new field of study. New methods of investigation—including the cultivation of bacteria in nutrient media, and inoculation experiments on animals—revealed new and startling facts as to the nature and modifications of the virulence of micro-organisms, which led to the discovery of means whereby they could be weakened at will and made productive against more potent forms.

The subjects of the attenuation of virus and the preventive action of inoculations with attenuated virus were then discussed, Pasteur's work being specially referred to. In regard to the present position of bacteriology, Sir Walter Foster said we had arrived at the following position. In some few diseases, such as anthrax and relapsing fever, we knew a specific micro-organism to be the contagium. In a second group, such as tubercle and cholera, the evidence was nearly complete. In a third group the position of the micro-organism as a cause of each malady was still *sub judice*. In scarlatina, for example, the existence of a specific germ had been warmly discussed by Klein and Crookshank. Edington claimed to have found a bacillus; Klein and others described a specific streptococcus. Fränkel and Freudenberg admitted the streptococcus, but said it was not special to scarlatina, but identical with the streptococcus pyogenes, which was common to many septic and purulent conditions. So the matter rested and it might be left with confidence in the hands of such workers, to whom he must add the name of Dr. Crooke, of Birmingham, who had the honor to have been the first to observe and describe a streptococcus in scarlatina. The lesson that these results taught us was that experiment and comparison had vastly changed our notions of disease, by substituting actual demonstrations of morbid processes for vague speculations. With these revelations of the nature of pathological processes, of the causes of disease, and of what we might call the mechanism of disease, was it any wonder that the attitude of the profession to disease was vastly changed? It was now time to ask, how did this changed attitude affect the problem of medicine—that twofold problem, the preservation of health and the cure of disease? On the latter branch his distinguished colleague, Dr. Broadbent, would address them on Friday. Turning to the first division of the subject Sir Walter Foster reviewed at some length the history of sanitary progress, and especially sanitary legislation, during the last half century. The concluding portion of his address was devoted to giving an account of some of the medical charities of Birmingham.

A vote of thanks to Sir Walter Foster for his address was proposed by SIR DYCE DUCKWORTH, seconded by DR. EDDISON, and carried amid applause.

The Middlemore Prize (in recognition of the best work in ophthalmic medicine and surgery) was then presented to Dr. W. A. Brailey, of London, and Mr. Priestley Smith, of Birmingham, between whom it was equally divided.

Army Medical Department.—The closing incident of the second general meeting was the presentation of some plate to Mr. Ernest Hart, in recognition of his services on behalf of the Army Medical Department. The presentation was made by Brigade-Surgeon Hamilton, on behalf of four hundred medical officers serving in India, who had subscribed to procure some valuable specimens of Indian workmanship.

The third general meeting was held on Thursday, when the "Address in Surgery" was delivered by MR. LAWSON TAIT. Mr. Tait's subject was threefold.

Surgical Training, Surgical Practice, Surgical Results.—In dealing with the first division of his subject he pleaded earnestly for professional training to be made more practical. Birmingham, he remarked, was a great home of industry, the very paradise of the handicrafts. Selecting one of the latter as an illustration, button-making, he said one might think that little skill would be required to cut an ivory nut into what they called blanks in a button-factory, but if you took the workman's place at the saw-bench, if you were not preternaturally skilful, it would only be after sacrificing a few of your fingers that you would find yourself behind him in every conceivable way. You would then begin to appreciate the principle of the subdivision of labor. In such an apparently rough, and certainly very humble, employment as that of the cutter of button blanks a few questions would help us to much thought, and the answers might excite in many of us solutions for problems greatly exercising the authorities of our medical corporations. You would find that even the cutter of the ivory nut would prove a more docile apprentice and a more competent workman if he had had a good education before he entered the shop. We further found that he must go through a long apprenticeship to accustom his eye to judge the nut, to avoid its faults, to accustom his fingers to the sense of resistance, and even his ear to the sound of the saw. Mere general education would do nothing of the kind for him, but the general training he had had would open his mind first of all to the sublime advantages of accuracy in all things, and it would make his mind just so much the more receptive for the monotonous details of his work.

Applying these remarks to the training required by the handicraft of surgery, Mr. Tait referred first to the value of a good general education, and said that if the student could spare the time and money to become a graduate in arts so much the better. Our apprentice surgeon had then to enter upon his purely professional training, and to learn the constituent parts of the body and their functions. Here came in our first difficulty. He, for one,

desired to raise his voice in protest against the absurd attention to detail and the enormous waste of time involved in the present biological training of the surgeon student. Let him be grounded in every fact of anatomy which might, under the rarest and most unlikely conditions, aid him to appreciate the results of an injury, or a displacement, or of a new growth; let him be grounded in all such items of information concerning the ultimate structure of organs and their mediate and immediate functions, and the changes to which disease subjected them. Let him be placed so constantly alongside somatic sections that he would not only learn his anatomy, but that he would never forget it. Let him see things and think of them so often that he would, as it were, see through his patient as the button-cutter saw through his nut before he cut it up. But he pleaded most earnestly that the successors of his hearers should be spared that senseless grind at useless details of anatomy with which their own young memories had been burdened—details which he could remember only by a demoralizing system of catch-words, details which he prepared himself to forget the moment the necessity of examinations was over. He remembered that they had to learn that the direction of the anterior cornu of one of the ventricles of the brain ran a course which was backward, outward, downward, forward, and inward, and they were enabled in the most improper way to remember these important facts by the word "bodfi." Had "bodfi" ever served any of his hearers at the bedside? Was there any conceivable condition of human accident or ailment in which "bodfi" could assist them to relieve their patients? The students who continued to learn such matters would find, as he had done, that they would be of no assistance to them to estimate the character of a delirium, and no amount of knowledge of the arrangements of the electrical currents in muscular fibre would help them to determine the proper relations of a splint.

In the old days—days which he could remember—it was charged against the corporations that they turned out a large number of ill-educated practitioners who knew nothing but their patients. The tendency now was to turn out a still larger number of scientific young tyros who knew neither patients nor their diseases till they had gone through a second pupilage, extending for years after they had left their university. This second pupilage lay in the rough school of experience, and in its second training they would be found deliberately and at once to throw overboard at least two thirds of what they had learned in the first. What the boy wanted after his general education had been fully developed, and his fundamental knowledge of useful anatomical facts and physiological principles had been made perfect to the utmost of their extent for usefulness and not one scrap beyond that, was that he should be dealt with as we dealt with the cutter of blanks in the button manufactory. He should be put at once in contact with his material. He therefore voted cordially with those who demanded the restoration of the apprenticeship system in such fashion as modern requirements indicated. It was, of course, to be no longer a seven years' slavery in mixing pills and spreading plasters, for the modern manufacturing chemist did all that for us now, but it should be a period of at least two years spent in learning how to deal with patients, how to divine their peculiarities, and in learning how to avoid making an ass of himself in the sick room, as the modern, newly-fledged, qualified assistant was certain to do for the first few years of his second pupilage, in spite of his biological lore.

He would carry the practice of apprenticeship farther. While the student was attending to this important part of his training he ought at the same time—and now he was speaking for those who had to follow the craft of surgery—to be taught how to use his hands. He would set him so many hours in the week into the shop of the village carpenter, and would have him trained to use a saw, a chisel, a plane, and a skew, so that he should be able to make a long splint, if need be, as well as to put it on. And he should also go into the blacksmith's shop till he knew how to strike properly with a hammer. Some of his hearers might think that to be unnecessary, but if they could look with a workman's eye (as he could do, for he served his time at the lathe, the bench, and the forge) at a Fellow of the College of Surgeons—he would not give his name, but he was to be found in almost every large hospital in the kingdom—who used a saw for the first time in his life in the amputation of a human leg, and saw, as he could see, what a horrible mess he made of his work, they would agree with him that a training in practical mechanics was just as necessary for a man who had to operate upon his fellow human beings as was a training in anatomy. The great difference between the man who started his saw cutting from the point of the saw and the man who started from the hilt was just as great—he thought it must be greater—as the difference between the man who amputated a leg without any knowledge of anatomy and the one who had such knowledge fairly perfect.

During the two years spent in practical training the student would unconsciously imbibe the fundamental principles of the scientific training which he would afterward have to undergo; he would see for himself day by day the characteristics of wounds healing healthily, and how different they were from those of a wound indicating action the result of constitutional poisoning. The meaning of these differences he would afterward learn at his clinical school. At present he could babble about the theoretical causes of the changes, but of the real facts and phases of them he knew nothing. After his apprenticeship, as he heard in the academical rooms the explanation of the process of the healing of a bone, he could recall to his mind illustrations in the practice which he had already gone through, and the combination of the facts as he knew them, with their explanation, would impress the whole thing on his mind in a way to which at present it was a complete blank. In medical education at present the cart was uniformly put before the horse.

Passing on to speak of the practice of surgery, Mr. Tait said that anæsthesia had been to surgery what steam had been for arts, manufactures, and commerce; it had revolutionized everything in connection with our art. The number of cases for operation increased vastly after the introduction of anæsthetics, and with this increase it became perfectly evident that no man could grasp the whole realm of surgical work. The subdivision of the work became inevitable, and the best and first example of this subdivision came in ophthalmic surgery. In abdominal surgery nothing was really done, if we excepted the truly brilliant achievement of Ephraim McDowell, before the days of anæsthetics. The greatest advance of all in the treatment of tumors—the intraperitoneal treatment of the pedicle by means of the cautery in the hands of Baker Brown, giving a mortality of ten per cent.—was the real starting-point of all our progress, and that proceeding would have been an absolute impossibility without the aid of an anæsthetic. Then came Spencer Wells, who established abdominal surgery as a specialty. Mr. Tait pointed out at some length how the arrangements in hospitals for the pursuit of surgery had been altered as the practice of surgery had grown.

Dealing next with the third division of his subject Mr. Tait said there was less clear ground on which to go. Surgical theories, he said, never led to anything. With regard to the antiseptic theory the last phase of the discussion was the antiseptic accoucheur, who pleasingly fancied that both his theory and his practice were new, whereas Semelweiss literally died for them nearly thirty years ago. Semelweiss had no theory, he simply stated the fact that puerperal women in Vienna were poisoned by dirt. "Wash your hands," he cried, "and the women will not die," and his colleagues ruined him for his frankness. But he persuaded the world he was right.

Mr. Tait then spoke of the desirability of publishing

accurate returns of hospital work and said that to Sir Spencer Wells was most undoubtedly due the credit of putting the publication of surgical results on a business-like basis. The extension of this ought to be encouraged in every possible way. Another great advance required was the devising of logical plans in recording and classifying the results and also the adoption of reasonable methods of conducting the investigation.

A vote of thanks to Mr. Lawson Tait for his address was then proposed by MR. TIMOTHY HOLMES, seconded by DR. MCLEAN (Michigan), and agreed to amid applause.

Gold Medal Presentation.—An interesting feature of the meeting was then the presentation of the Gold Medal of the Association to Surgeon Parke, who was received with great enthusiasm. In acknowledging the presentation SURGEON PARKE said it was his greatest gratification to know that his services in connection with the Emin Pasha Relief Expedition had been appreciated by the members of the profession to which he had the privilege to belong, because he knew none more critical and no better judges of the difficulties which had been overcome. For six thousand miles the only means of transport was on the heads of men. He felt no less gratification from the fact that after three years' marching across Africa he had retained the good will of his wonderful chief and his brave companions. One of the brightest features in connection with the expedition was the good feeling which existed among the Europeans and between the Europeans and the blacks. They all entered Africa strangers to each other, and after their three years' wanderings emerged from the Dark Continent fast friends. Among the Europeans the mortality during the expedition was exceedingly small; only two out of fifty died, and of these two one was murdered and the other died about six hundred miles away without any medical attention. Among the black people they only brought back 300 out of 700. During the starvation period—the period of the greatest distress—the white people appeared to get along much better than the black; they had more pluck, more energy, and more love of life than the black people, who had very little resistive power. They found Emin Pasha and brought him back to the coast. Everyone knew what had happened to Emin since then; how he had walked out of a window and severely injured himself. He had not been in a two-story house for years, so there was little wonder that he mistook the window for a door. They all knew what had since happened to Mr. Stanley. In conclusion, Surgeon Parke spoke of the fine country in the centre of Africa; it was a beautifully fertile region, a lovely garden. He did not doubt that in a short time it would be opened up to civilization, for no less than three railways were being constructed to approach it. The native races, too, were not all ugly. The Wahumas were really handsome, and if some of the Wahuma ladies were to be introduced into England he believed there would soon be a great emigration of enterprising colonists to Africa.

The fourth (and concluding) general meeting took place on Friday.

An Address on Therapeutics was read by DR. BROADBENT, of London. After thanking the Council of the Association for the honor conferred on him by assigning to him the lecture on therapeutics, Dr. Broadbent said he could lay claim to only one quality in accepting the honor, and that was that he had an immense interest in the subject as a branch of science, and not only as a professional means of gaining a living. He had a profound conviction that, in the therapeutic art, there must be fixed laws, if only those could be discovered; and that, sooner or later, the art of therapeutics would enter the scientific epoch, and be ranked with arts such as engineering or other arts which applied the exacter sciences to the benefit of mankind. He believed that, just as in engineering, a knowledge of material was essential to the successful constructor, so in therapeutics the common sciences of physics and chemistry would eventually be found capable of explaining the actions of various agents upon the human body.

Therapeutics, of course, must advance by means of experiment and experience, and was less of a deductive art than many others were. Unfortunately, there was but little constancy observed in the effects of remedies; because the effect varied so much according to the constitution of the patient on whom they were tried. Organisms varied enormously. Then, again, a drug would often have quite different effects when put into a full and into a fasting stomach. In the former case the system was occupied with its nutrition, and in the latter the substance would be taken up at once and produce its full effects. And in giving drugs to different animals it must be remembered that as in the case of the carnivora the food was so different from that of the herbivora that substances which would have a powerful effect on one kind of feeders might have none on others. In the liver-cells, for instance, of the herbivora, which had so much more work to do, the effect of any special drug might be expected to be quite different from what it would be in a less busy set of cells in carnivora. Again, the functional endowments of the brain were incomparably greater in some animals than in others, and it was only natural to conclude, *à priori*, what was well known to be the case in fact, that nerve-poisons acted very differently on vertebrate and invertebrate animals, and on some of the former far more than on others. Some of the higher animals had most active brains, and strychnine acted very differently on the brain of such animals, while all of them were similarly affected by that drug as far as the spinal cord was concerned. When the vertebrate animals, however, were excluded it was found that strychnine was no poison to beetles, at least he had been told this by a chemist, who had falled to poison these insects by using strychnine, which was so deadly to mammalia and other vertebrates.

From facts such as these, induction in therapeutics was clearly surrounded by peculiar difficulties. But it must be remembered that the motions of the planets round the sun had remained unaccounted for until the day when the theory of universal gravitation was explained by Newton; and if therapeutics were ever to become scientific we must try to get a definite idea of what it was that we were aiming at. Some persons looked upon the effects of quinine on ague, of mercury on syphilis, etc., as ultimate facts. If this were so there could be no science of therapeutics. By the word therapeutics he included all the agents which attempted to adjust the body to its environment, and he quoted Mr. Herbert Spencer's definition of health as being such an adjustment. A living organism was ever subject to disintegrating processes which it was continually resisting. Health varied in degree. The health of young persons differed from that of old, and the health in cold climates differed from that in warm. So long as the adjustment between the body and its environment continued to be complete health existed, but when it was incomplete disease supervened. The vomiting and purging which took place where indigestible food was ingested were efforts of the system to readjust itself to its environment. A fragile constitution was one which was ill-adjusted to its environment. Such an one would sometimes carry the patient through a long life if there be but little hardship in his lot; but if storms arise, the life was often rapidly sacrificed. There was also continuous adjustment of the various cells in the body to their environment going on in the interior of the body. With such a view as this it was clear that acute disease must be regarded as a process by which the organism was endeavoring to adjust itself to its environment. And thus it might be asked whetheri n fevers the excessive heat might not be one way in which the system tried to protect itself, or to eliminate the poison. The enormous increase in the number of micro-organisms in the blood might account, together with the ptomaines engendered by them, for the high temperature. In such fevers our object would evidently be, first of all, directed, if that

were possible, to destroy the microbe; but when that was not feasible it was not advisable always blindly to interfere with the fever, since, if the organs could be protected by the process of fever, health might ere long be restored. In febrile disease, to lower the temperature was not always synonymous with cure of the disease. Thus, although antipyretic treatment and cold were useful in typhoid fever, they were of no service in pneumonia. Drenching with cold water and using cold enemas might prove useful in some fevers, but hurtful in other cases of high temperature. The different drugs which were at present so fashionable for lowering the temperature were often doing much harm as well as good, since the remedy, while it lowered the temperature, might, at the same time, prove very lowering to the strength of the patient. At the outset of pneumonia, however, before the attack fairly set in, antipyretic remedies, in his experience, might occasionally cut short the disease. The evolution of energy in the body went on at the cost of disintegration of the tissues. In warm-blooded animals a certain temperature was necessary, and heat was the great intermediary through which nutrition was turned into energy. Heat was the least specialized of all the forms of energy. In disease the energy which ought to go to the building up of the tissues was given off in the form of heat. On this point he begged to refer to Dr. Harry Campbell's work on the etiology of disease. The limits of our power in therapeutics were these: We could not make the tissues of old people act like those of the young. A single dose of some drug might modify the environment of the tissues, and tend toward recovery from the disease. The hospital patient had many changes of a most useful kind. He was removed from what were frequently most unhygienic surroundings to the airy wards of a hospital, where good food, careful and kind nursing, and other great changes were secured for him.

Again, the over fed wealthy man had a great change when he was put to bed and compelled to live on slops or low diet. But the real function of the physician lay in the use of drugs, and to depreciate the use of such forms of the therapeutic art was most erroneous. No work was more valuable in this connection than the labors of the experimental physiologist when he studied the action of drugs. Thus, when it became known that digitalis acted on the muscle of the heart a flood of light was thrown upon its utility in diseased states of the organ. It was quite delightful to see with what enthusiasm many inquirers threw themselves into this very fascinating branch of the therapeutic art. In this experimentation the method of differences, the true way of discovering causation, could be made use of. The results that this method promised were most hopeful. With regard to the use of chloral and opium as yet our knowledge was merely mediate; but the explanation of the action of these drugs would eventually be afforded by the deductive method. All physiological action of drugs depended on chemical laws. The effect of small and large doses was different, and this might be compared to the action of strong sulphuric acid on starch, which it charred and destroyed. There must also be a quantitative relation between a drug and its effects. Just as when alcohols are more or less fluid or solid the effect on the system was increased or decreased. Dr. Broadbent then adverted to Dr. Williams' experiments on zanthine, caffeine, and theobromine. Zanthine, that observer found, paralyzed the spinal cord. Theobromine had a similar effect, and a tetanizing action on the muscles. The tetanizing effect was due to its molecule being heavier by the substitution of methyl in place of hydrogen. Drs. Crum Brown and Fraser's experiments upon the chemistry of morphine were next alluded to. The chemical constitution of this substance had not yet been made out very perfectly. When chloride of methyl was added the effect of the drug was altered. The most remarkable inorganic group of remedies was that of arsenic, phosphorus, and antimony. In anæmia, arsenic and phosphorus were both of service. In skin disease, also, both of these drugs might be useful. Bismuth was inert, because insoluble, and the emesis caused by antimony marked its effects on the skin. A preposterous prejudice existed against the use of phosphorus. The dynamic action of this drug was produced by the passage of phosphorus into its oxides. In its allotropic form the drug was inert, and an ounce of phosphate of soda was of no effect on the system. The hypophosphites were of more use, because oxidizable. The arseniates were powerful because of their great affinity for hydrogen. Mercury was useful in therapeutics because it was a deadly poison to so many micro-organisms. Tartaric acid, on the other hand, was not a foe to lowly organisms, and therefore no antiseptic. Chemical groups might probably have corresponding therapeutical groups in some cases. But no set of chemical bodies could be more alike than chlorine, bromine, and iodine, and yet iodide of potassium was of far greater utility than chloride of potassium. The reason of this was that the iodide was insoluble and could easily be made to yield up its iodine in the blood and then became oxidized in the system. Bromides in epilepsy had probably nothing special in their action, but merely acted by their chemical effect on the oxygen or hydrogen of the tissues. With regard to the alkalies, soda was found in the serum and potash in the corpuscles of the blood. Other elements might be found to have similar therapeutical characters. Thus lead and soda had probably some similar action. Imagination was useful to direct the way in which investigations might be made. With regard to the quantitative relation of effect between a substance used and its effects, there was some difficult problems remaining to be solved. Thus it was certainly mysterious that one grain of hydrocyanic acid should be so destructive to life. The quantitative value of nerve force, however, was very low, and it was characterized by intensity rather than by strength.

Carbonic oxide resembled grit in the wheels of an engine, and the action of prussic acid was like that of an explosive. One remark was to be made, and that was that the great poisons were all of the nitrite type, and considerable chemical tension existed in that group of chemical substances. In conclusion he would remark that therapeutics were most safely applied by those who possessed profound physiological knowledge. It was bad practice to be continually using purgatives, stimulants, or narcotics. When the urine was turbid, it was not sufficient at once to prescribe an alkali; and it was short-sighted policy to continue giving bromides indefinitely in epilepsy. If this was done, the health of the patient might be deteriorated with no benefit to the fits. As much as possible, the practitioners must resist the desire for palliatives. He protested against the insensate rage for new drugs. This rage was absolutely fatal to rational advance in therapeutics. Fraser's strophanthus was an advance; but the host of remedies sent out by advertising chemists were most dangerous. Podophyllin and mercury were both said to act on the liver; but they did so very differently, and it required a most discriminating practitioner to know when to use either. Finally he would lay down as a test for a weak therapeutist—a constant running to drugs and a fondness for the most novel drugs to be obtained in the apothecary's shop.

A vote of thanks to Dr. Broadbent for his address was unanimously awarded, and the usual votes of thanks were then passed to the various officials, after which the proceedings terminated.

Much Dissatisfaction at Arrangements.—I regret to chronicle that much dissatisfaction has been expressed at some of the arrangements made. It seems that some delegates have been treated with discourtesy on presenting their credentials. The president and reception committee should have prevented this. When a medical man comes from a college or a university at a distance officially delegated in response to an invitation it is inexcusable to leave him to a paid official of defective

manners. The same delegates will go to Berlin, and we may look for some rather unpleasant comparisons to be made between English and German courtesy. I hear also that no little dissatisfaction is felt at garden parties being given, and announced in the official programmes, but invitations to them issued privately. I have heard it remarked very pointedly that entertainments which are officially announced should be open to all members. Let us hope for better arrangements next year.

SECTION OF MEDICINE AND THERAPEUTICS.

WEDNESDAY, JULY 30TH.

DR. DRUMMOND, of Newcastle, occupied the chair. Sir Dyce Duckworth had been summoned to London, and could not act as president.

Varieties of Cirrhosis of the Liver.—DR. SAUNDBY, of Birmingham, opened the discussion upon the varieties of cirrhosis of the liver. The author said he presumed he had been asked to open this discussion partly because he had written a book on the subject. He then sent round the following table as a short synopsis of his views as to the varieties of hepatic cirrhosis.

TABLE I.—*Anatomical Changes in the Varieties of Hepatic Cirrhosis.*

Varieties.	Size.	Color.	Surface.	Capsule.	Consistence.	Bile Passages	Position of New Growth.	Newly-formed Biliary Canaliculi.
Alcoholic	Usually small.	Pale olive.	Granular.	Thick.	Tough.	Nearly empty.	Round groups of acini.	Present.
Cardiac or cyanotic	Usually large.	Dark.	Smooth.	"	"	" "	In centres of acini.	Absent.
Biliary	" "	Olive or pale.	"	Slightly thick.	"	Dilated and full of bile.	Around acini. single	Abundant.
Diffuse syphilitic	Large.	Brown.	"	Opaque.	"	Normal or empty.	Diffused.	A few only.
Gummatous	Irregular.	Pale.	Irregular.	Thick and opaque in places.	Cartilaginous in places.	Normal.	Irregular.	Absent.
Tubercular	Large	Pale or normal.	Smooth	Normal.	Normal.	"	Around acini. single	Very abundant.
Malarial	"	Dark pigmented.	"	"	Tough.	"	Around acini. single	Absent.
Scarlatinal	Normal	Normal.	"	"	Normal.	"	Around acini. single	"
Rachitic	Large.	Pale.	"		Tough.	"	Around acini. single	Present.
Diabetic	"	Dark and pigmented or pale.	Granular or Thick. smooth.		"	"	Generally in centres of acini.	Absent.

TABLE II.—*Clinical Features of the Varieties of Hepatic Cirrhosis.*

Varieties.	Age.	Sex.	History.	Ascites.	Jaundice.	Hæmatemesis.	Size of Liver.
Alcoholic	Adult.	Usually male.	Abuse of alcohol.	Present in two-thirds.	Absent until later stages. A subicteric tinge then only.	May occur.	Usually small.
Cardiac or cyanotic	Any age.	Either.	Chronic heart disease.	Not uncommon.	Occasional late.	Absent.	Enlarged.
Biliary	" "	"	Early jaundice.	Absent.	Present and persistent	"	"
Diffuse syphilitic	Childhood.	"	Hereditary syphilis.	"	Absent.	"	"
Gummatous	Adult.	"	Acquired syphilis.	May occur.	Occasional.	"	Irregular.
Tubercular	Any age.	"	Tubercular disease elsewhere.	Absent.	Absent.	"	Enlarged.
Malarial	" "	"	Prolonged malarial infection.	"	Frequently present.	"	"
Scarlatinal	Usually in childhood.	"	Scarlatina.	"	Absent.	"	Normal.
Rachitic	Childhood.	"	Rickets and chronic gastro-intestinal catarrh.	"	"	"	Enlarged.
Diabetic	Adult.	Usually male.	Diabetes.	"	Absent, but skin may be bronzed.	"	Generally enlarged.

Under the microscope were placed slides illustrating the varieties of cirrhosis mentioned in the paper.

Modern pathological investigation has distinguished ten varieties of cirrhosis of the liver, viz.: 1, Alcoholic; 2, cardiac; 3, biliary; 4, diffuse syphilitic; 5, gummatous; 6, tubercular; 7, malarial; 8, scarlatinal; 9, rachitic; 10, diabetic. Some of these forms, notably the tubercular, the scarlatinal, and the diabetic, have no clinical history whatever, and this also to a considerable extent is true of the cardiac and gummatous varieties. In all of these the lesion may be so slight as to give rise to no signs during life except some enlargement of the liver. On the other hand, their naked-eye and microscopic appearances are usually characteristic and readily recognized post mortem. These are illustrated by specimens of livers and microscopical sections.

Clinical interest centres in the alcoholic form with its usually well-marked symptoms. But it is important to note that this, too, may exist without causing such derangement of health as to call for medical assistance. In these cases there is no ascites, but there is a great liability to death from hæmatemesis, due to the rupture of the dilated gastric or œsophageal veins by which the blood from the portal system reaches the superior vena cava. Yet the condition of these patients is greatly to be preferred to that of those who, swollen with ascites, are wholly invalided. It is therefore desirable to attempt to reduce the latter to the former condition. This may be done by early and repeated tapping, and a case of six years' standing is shown to illustrate it. Pathological specimens of the varicose, gastric, and œsophageal veins are also exhibited.

The not uncommon termination of alcoholic cirrhosis with symptoms of malignant jaundice is emphasized. The symptoms, where any occur, and pathological characters of the other forms are briefly sketched.

Special attention is directed to rachitic cirrhosis, which is frequently supposed to be syphilitic—a view that receives some support from the benefit derived from the use of mercury (calomel or gray powder) in small doses.

Alcoholic Cirrhosis.—The first variety, or alcoholic cirrhosis, was the most commonly met with, and had been first described by Laennec. This form of cirrhosis was usually met with in adult males and was distinctly due to the use of alcohol. In this form of cirrhosis it was noticeable that those patients who had hæmatemesis escaped ascites, and, on the other hand, those who had ascites usually escaped hæmatemesis. As symptoms of alcoholic cirrhosis there were to be mentioned various forms of dyspeptic symptoms, subicteric discoloration of the skin, sometimes going as far as jaundice. The presence of urobiline in the urine was a notable feature. There was nothing in the condition of the spleen pathognomonic of the disease. That organ was usually enlarged in alcoholic cirrhosis. Ascites was present in a large percentage of all cases of alcoholic cirrhosis. But this was by no

means always the case. Dr. Saundby mentioned the case of a man with hæmatemesis who, when examined post mortem, had had typical hobnailed liver, although he had never exhibited any ascitic symptoms. In that case there had been great dilatation of the collateral veins. As a rule, then, the opening out of the collateral circulation, which gave rise to hæmatemesis, was likely to free the patient from ascites. As to the pathology of this form of cirrhosis, the new formation spread through the canals and probably sometimes affected the acini. Dr. Saundby then explained that, by means of frequent tapping, many such cases of ascites might be cured for a shorter or longer period. He introduced a patient who had six years ago had ascites and had been frequently tapped for it. This man was now in fairly good health, and went to his work regularly. He, however, continued to drink about three pints of beer daily, but no gin or other spirit. The man looked sickly, but was in a condition which, if he had been rich, would have been considered quite satisfactory. Many of the patients were hopeless drunkards; but even in these a year or two of comparatively good life might be hoped for by tapping. Dr. C. Murchison was the first to recommend repeated tapping as a treatment in alcoholic cirrhosis. In these cases tapping should be repeated time after time. This was a great novelty in modern times, for when he was a student it was the custom to give a diuretic or purgative in cases of alcoholic cirrhosis, and then, if these did not succeed in removing the fluid, the case was considered hopeless and left to die. There were, he knew, many who made use of the practice of repeated tapping; but even yet there were very many who did not avail themselves as much as they might with advantage do of this slight operation.

Cardiac Cirrhosis.—With regard to cardiac cirrhosis, that was clinically of but slight importance, as it led to no symptoms and was merely caused by the congestion of the liver accompanying chronic bronchitis or other affection of the lungs and heart. The liver in such cases was enlarged and tender. There was frequently slight jaundice. The new growth spread from the radicles of the hepatic vein.

Biliary Cirrhosis was an interesting form of the disease and not so well-known as alcoholic cirrhosis. It was of the hypertrophic variety. Charcot said that such hypertrophied livers might subsequently become contracted. There was in this case proliferation of the bile-ducts. The prognosis was very unfavorable and terminated in death. Ascites was for the most part absent as a symptom of this form of cirrhosis.

Syphilitic Cirrhosis was most met with in children with inherited syphilis. The liver in such cases was smooth and tough on section. This was a diffused lesion, attacking the liver-cells by cell-growth. Its treatment was antisyphilitic in character.

Gummy Cirrhosis hardly deserved the appellation of cirrhosis, and the prognosis was unfavorable only in severe cases. Under the microscope the fibrous tissue was seen around the cells.

Tubercular Cirrhosis was so little recognized that he almost expected that its existence would be denied. However, it certainly occurred, and he had met with two cases of it. The liver was large and smooth in such cases, and there was trabecular network around the lobules. There was enormous development of the biliary radicles in one case.

Malarial Cirrhosis.—In such cases the liver was often enlarged and pigmented. This complaint no doubt arose from frequent malarial attacks. The lobules were invaded, as well as surrounded, by the new growth in this affection.

Scarlatinal Cirrhosis was only known to pathologists.

Rachitic Cirrhosis was sometimes noticed in rickety children. Gastro-intestinal catarrh was a symptom of this form of the disease, and it resembled in some respects hereditary syphilis of the liver. The spleen was enlarged in these cases.

Diabetic Cirrhosis.—The description of diabetic cirrhosis was due to French pathologists. It was certainly a rare affection. It was not very rare to see some amount of cirrhosis in the livers of patients dying of diabetes. Hanot mentioned that this form of cirrhosis commenced in the hepatic radicles. The condition was often associated with bronzing of the skin. The most common form of alcoholic cirrhosis was often hypertrophic at first. Dr. Saundby concluded his paper by explaining that he had taken the method of classification by causation as the most useful.

Dr. Stacey Wilson said that it seemed useful to call attention to the condition of dilatation of the veins at the root of the œsophagus in cirrhosis, by which the collateral circulation was often carried on. In such cases there was a plexus of veins around the œsophagus at its entrance into the stomach. The capillary veins might be seen passing up the cardiac sphincter. The sphincter of the œsophagus was of great importance when the portal vessels were obstructed. As soon as large varicose veins in the œsophagus ruptured, hæmatemesis occurred. Such cases were rarely mentioned in text-books. Probably in the future this would be found to explain hæmatemesis. Lauvel, in 1840, was the first to point to this class of cases; but he thought that Bristowe was the first English physician to give cases of it. During the last ten years twenty cases of this dilatation of the œsophageal veins had been published, but ten of them had been due to two observers. He himself had seen five cases. Why had this lesion been so overlooked? The reason was that the œsophagus was rarely examined in the post-mortem room. When the veins were collapsed, too, there was very little evidence of their existence. To look for them satisfactorily it was necessary to inflate the veins by means of the blow-pipe. A man might go on well for years, and suddenly have hæmatemesis, and this might cease and the patient might go on with his work as usual. As to treatment, when a vein was ruptured in such a case, it was well to prevent the patient from performing the act of deglutition. Perhaps the use of nitrite of amyl might be of service in these cases.

Dr. Radcliffe had had three cases of alcoholic cirrhosis in which he had been able to recognize the existence of varices in the œsophagus. The first of these cases had been under the care of Dr. Saundby. One patient had hæmatemesis, and died a few days afterward, when his liver was found to be waxy, syphilitic, and cirrhotic. The œsophagus was removed, and its veins were found to be dilated and varicose. In another case under the care of Dr. Saundby the man was in hospital a fortnight and had had marked melæna. On making a post-mortem examination in this case it was found that the posterior wall of the stomach near the cardiac orifice was covered with varicose veins, and these extended into the œsophagus. At the post-mortem examination no great varicosity was seen until the veins were blown up. In another case there had been no hæmatemesis, but the motions had been mixed with blood. In none of these cases was there any capillary oozing from the walls of the stomach.

Dr. Thomas, of Bournemouth, had listened to the paper and to the other two descriptions of œsophageal dilatation of the veins. He thought all of these papers would be likely to produce an influence upon treatment in the future. It would be of great importance if it were possible to diagnose the existence of cirrhosis in its early stage. When he was hospital interne he used to notice that many of his patients suffered from hæmorrhoids, diarrhœa, and sickness in the morning, with constant spitting and hawking. They were apt to suffer from pneumonia or bronchitis and when death took place the liver was found to be cirrhotic. Other similar patients would get thin, and then exhibit ascites. The question was whether the latter class of cases was the same as the former or not. At first in these cases the liver was hy-

pertrophic and afterward atrophic. Patients in private practice had hypertrophic livers, which ended in cirrhosis with dropsy. These patients drank beer to a great extent. To decide this question would be a great boon to the public.

Dr. Drysdale had been greatly instructed by the paper read by Dr. Saundby, and by the classification he had made according to causes. That kind of classification was certainly the most practical, and, of course, in the medical section the great question was how to cure patients. In the other sections questions of pathology were more in place. The most important causes of cirrhosis met with in ordinary practice were, firstly, and far above all other causes, alcohol; then came syphilis, heart disease, and malaria. But, naturally, the discussion had been entirely confined to the question of alcoholic cirrhosis. This was fortunate, as it was both the most curable and the variety which was constantly coming before them. His impression was that it was sometimes possible to surmise the existence of cirrhosis of this description when the patient had been a drunkard and had enlargement of the liver, vomiting, and other symptoms of alcoholic poisoning. With regard to the prognosis of ascites of alcoholic origin, that had of late years been better than it used to be, the practice of repeated tapping and the relief obtained in this way had been a very great advance in therapeutics. It was his experience that in the hypertrophic variety of cirrhosis there was a better chance of ultimate recovery than when the atrophic form existed. Probably in the former case a larger number of liver-cells were healthy and capable of carrying on the functions of the organ. With regard to the variety of cirrhosis called bilious, that, in his experience, was uniformly fatal in its prognosis. In ascites the patient should be made to refrain entirely from alcohol, and should have the fluid drawn off as often as was needed for his comfort. It was well to give a whiff of chloroform when the puncture was made, since patients shirked the pain of the cut, and often refused the operation too long.

Dr. Broadbent, of London, said he had been greatly instructed by the specimens of venous affections of the œsophagus shown by Drs. Radcliffe and Wilson. He had no idea that these affections played such an important part in the causation of hæmatemesis. It had never been his practice to stop hæmatemesis by styptics.

Dr. Hanford, of Nottingham, thought that another variety of cirrhosis might be added, and that it might be styled interstitial hepatitis. He also thought that there was a febrile variety, and enteric fever might be followed by cirrhosis. There were now quite a list of histories of cirrhosis among children. Diabetic cirrhosis was a real entity and capillary dilatation was the essence of this variety. The liver-cells were much atrophied in such cases. Diet was of great importance in the treatment of cirrhosis and should be vegetable in character. Some of the cases cured by repeated tappings were connected rather with peritonitis than with cirrhosis.

Sir William Moore was not certain that such a condition as that of malaria existed. When the liver was congested in the tropics, it was enlarged. He doubted the existence of malarial cirrhosis.

Dr. Griffiths spoke of large veins passing from the portal vein to the umbilicus. The question of the collateral circulation was of prime importance. The publican usually died of large liver. The test for the size of the liver by percussion was a very bad one. Ascites was not always due to cirrhosis of the liver, and possibly, in the case exhibited by Dr. Saundby, some other affection had existed. Dr. Russell said the typhoid form of cirrhosis was common. As to repeated tapping, he remembered a case where tapping was repeated so often that there was no more room for the fluid to accumulate in.

Dr. Hutchinson, of Scarborough, said the long array of causes presented by Dr. Saundby was really terrifying. His only consolation was that none of them except alcoholic fluids seemed to have any symptoms. Alcohol was indeed at the bottom of all the clinical cases of cirrhosis. He wished to protest against the way in which patients were sent off to foreign countries with cirrhosis of the liver. In the case of a gentleman thus expatriated he suffered terribly from sea-sickness and died on arriving at Algiers.

Dr. Drummond mentioned the case of a patient in whom cirrhosis of the liver seemed to have followed after swallowing much tobacco-juice. He also mentioned a case of acute alcoholic biliary cirrhosis in a man aged thirty-four, who caught cold and died in a few days. The liver weighed six and one-half pounds, and profound biliary cirrhosis was found on post mortem examination.

Dr. Saundby said that Dr. Thomas had suggested that cirrhosis of the liver might be diagnosed during life by means of the sickness and other symptoms of gastro-intestinal catarrh, and that hypertrophic cirrhosis might be caused by beer drinking. But spirit-drinking also might cause this. As to tapping, the whole of the fluid might always be slowly withdrawn.

The Section then adjourned till next year.

SECTION IN SURGERY.

Wednesday, July 30th.

Chairman's Address.—Mr. T. H. Bartleet, of Birmingham, in opening the business of the Section, remarked that the town in which they met was a well-equipped surgical centre. There was plentiful accommodation in the hospitals, both general and special. In a sketch of the medical charities he mentioned the fact that the road to the General Hospital, although now in the midst of a densely populated district, was formerly marked by sign-posts, to guide the sick poor to its gates. Among past distinguished Birmingham men he mentioned Freer, who was the first to tie the external iliac artery, and James Hodgson, who wrote a classical work on arteries, and who subsequently became President of the College of Surgeons. At the present time Queen's College anatomical museum was a monument to the skill of Professor Windle. The speaker insisted on the importance of teaching operative surgery, a plea which would be at once accepted by experts. It was a common experience for surgeons to spend years after starting in acquiring the art of surgery. Twenty or thirty years ago surgery lay in the hands of the few. Operation was rarely attempted by the general practitioner, and cases drifted into the hospitals of the large towns. Now that was all different. Surgery was no longer the fetish it used to be. England was behind most continental countries in the average requirements of operative surgery, both in education and in examination. She was behind America and Ireland in this respect, and even in the fellowship examination of the College of Surgeons it was of minor importance. The cost of such training was heavy, not only in money, but in time and labor. The cost of subjects also made examination a costly matter. There could be no doubt, however, that the extended teaching of operative surgery would prove a benefit to our students, to our schools, and to suffering humanity.

Surgery of the Larger Arteries.—Mr. Timothy Holmes read a paper on the "Surgery of the Larger Arteries." He said that ancient proposals, discredited half a century ago, were again revived. We were now asked to return to the soft, broad ligature of olden times in the shape of kangaroo tendon or ox aorta. Then the old surgeons approximated and did not cut the walls of the vessel. There was the old practice of Abernethy and his colleagues, who divided the vessel between two ligatures, now revived, chiefly at St. Bartholomew's hospital. Lastly, there was the revival of Auel's operation of tying close to the sac in popliteal aneurism.

Materials for Ligatures.—As to the materials for ligatures, it was useless to recount the old experiments of Cooper and others. Then suppuration was the rule and the ligatures came away by ulceration. Now a ligature was not exposed to those conditions. A ligature should

be firm and unirritating, soft enough to be easily tied, and able to retain the knot after cutting off short. It should also be broad enough to close the artery without injury to inner coats. Silk appeared to fulfil all these conditions. It was unirritating and absorbable without suppuration. Catgut was handy but not trustworthy. Ox aorta was used in 1879 with admirable ease and success in tying the external iliac artery. Ligatures of the last mentioned and of kangaroo tendon were less easy to tie than silk, a fact which explained its looseness in certain cases. It was also difficult to make sure of apposing the coats of the vessels. In the first case tied with ox aorta the artery became pervious. Catgut was better for the cut ends of vessels, because there was no liability to slip. The animal substance was prepared by nature instead of being left to the uncertain process of the instrument-maker. In one case where catgut and ox aorta were used on the same patient the tendon was found post mortem to be embedded and infiltrated with cells, though still maintaining its grasp, while the gut had disappeared. In another patient who died of secondary hemorrhage from the distal end of the carotid, the tied portion of the vessel was entirely obliterated, and the ligature gone. The ulceration that had taken place was due to other causes. Ballance and Edwards did not regard silk as perfect for aseptic ligatures. In silk the structure was continuous throughout; it did not split; and absorption took place from outside. While they were prepossessed in favor of animal substances, Savory upheld silk ligatures. Silk, however, was unreliable if the artery was to be tied and the ligature buried. He agreed with Bennett May that silk at best could not be relied upon. Kangaroo tendon was trustworthy for two months, well prepared chronic catgut for one month. Of all materials in use, he personally preferred ox aorta.

Amount of Force to be Applied.—There was then the question as to the amount of force to be applied, whether it should be the aim of the operator, with Hunter, to stop the circulation, or, as Jones proposed, to divide the inner coats. For a long time Jones attempted to obliterate the artery by a process equivalent to union by first intention. Comparing the behavior of buried ligatures with long ends brought out of the wound, the latter were bound to ulcerate their way out. He intended to avoid the subject of secondary hemorrhage, as he knew no instance where it had occurred when all parts healed quickly. To avoid all disturbance around the ligature was, in his opinion, most important toward securing rapid union. Ballance and Edwards proved that it was not necessary to success in lower animals to cut the inner coats. Hunter's experiments were fairly successful, astonishingly so when we remembered that he tied the vein as well as the artery. Barwell tied successfully the subclavian and the carotid, dividing the inner coats. Many surgeons admitted the possibility of successful ligature without formation of internal clot. Pick said it was not absolutely necessary, but still desirable. Closure was effected by a membrane; there was effusion and proliferation round the cut ends, aided or not by division of the inner coats. Whether such division made the cicatrix that closed the artery firmer or not was still undecided.

It was more difficult to tie animal ligatures than silk. The method introduced by Abernethy of tying the artery in two places and dividing between them, lately revived at St. Bartholomew's, had existed from the earliest times, chiefly in wounds of vessels. The chief reason advanced was the assumption that large arteries did not ulcerate. The plan prevailed for twenty years or more, and was replaced by the simple ligature, which, when used without disturbance of vessels, was satisfactory. Cooper applied only force enough to cut coats. Lately a patient died at St. Bartholomew's from the slipping of the upper ligature. That possibility constituted an additional danger. At the present day stumps heal rapidly and arteries do not ulcerate. In earlier days prolonged suppuration and ulceration were the rule. Secondary hemorrhage was now very rare. Out of 23 ligatures of large arteries at St. George's there was only one case of secondary hemorrhage, but of 11 such cases Abernethy had one of hemorrhage in a suppurating wound after twenty-one days. It was difficult to see why two ligatures should produce less irritation than one. Savory found that the whole length of the artery was not rendered impervious by ligature in Hunter's canal. Hulke avowed that the artery was occluded down to the aneurism. Most modern text-books adopted the view that it was impervious for three or four finger-breadths below the ligature, there was then a free space and it was again obliterated. Hodgson found no case except Cooper's of entire obliteration. In Hunter's original case the artery was open between the point tied and the aneurism. Savory had settled that obliteration was needed only at the point tied. Ligature of the trunk left almost necessarily a portion unobliterated. In the alternative of tying near the aneurism the risk of diseased vessels was exaggerated. In subclavian and axillary arteries the ligature must be near the aneurism where the probability of atheroma was far greater. Surgical aneurisms were rare and could be treated successfully by Hunter's and other methods. Simple aneurisms were always curable by simple means. In very large and rapidly growing aneurisms Auel's method was more dangerous. Tying the popliteal, however, was not so formidable in these days of buried ligatures and aseptic surgery. Annandale recommended ligature of the superficial femoral in all such cases as rapidly growing or inflamed aneurisms, or those attended with joint or other complications. He said that he had never known a case of secondary hemorrhage where the old operation had been carefully done antiseptically. Auel's operation, then, he regarded as unnecessary in most cases.

As to Secondary Hemorrhage, Harrison Cripps' statement that it occurred in eight per cent. was true up to that time, but did not apply under altered surgical conditions. Ligature of the large arteries was comparatively rare. At St. George's there had been six cases only of ligature of the femoral in five years. However, the experience of any single hospital was often fallacious. Secondary hemorrhage was now very rare, and would become still rarer with each simplification of treatment. Syme, without antiseptics, cured twenty-three cases. The first great treatment of secondary hemorrhage was by pressure. In the sudden detachment of ligatures it was best to take up the vessel. He would dissuade ligature of the iliac. Prevention was all important and the broad aorta ligature was most desirable. Lastly, under modern advances in surgery all the operative measures alluded to could be undertaken with confidence.

Mr. Bennett May, of Birmingham, said the ideal was to obtain rapid union of wound over ligature, so that the process might be subcutaneous. Silk could not be relied on equally with animal ligatures. In his experience the sinus often remained after using silk. With simple gut he thought it essential to divide the inner coats. There was a question in his mind between chromic and ordinary gut. He had seen chromic gut come away unaltered three or four months after ligature. Catgut he had found successful in all but the largest arteries, such as the innominate. It should be tied tightly and round gut should be used. With silk it was advisable to leave the ends out. Some chromic gut might fulfil all conditions, but the surgeon was very much in the hands of the manufacturer. Failure in tying the innominate was due to the wound being ill adapted for early union and constant motion of the chest. Ox aorta was too elastic to be tied sufficiently tight, and was apt to break at the moment of highest tension in big vessels. In future he should use kangaroo tendon for the innominate, and would close the wound at once without drainage-tube.

Mr. Herbert Page mentioned several cases of double aneurism. He had treated many cases successfully under old methods in 1870, when there was no exorcism of germs.

DR. W. THOMSON, of Dublin, said that there were no new proposals; it was a choice between old methods. Most surgeons of the present day thought it necessary to use a broad ligature, causing obliteration of vessel. The conditions of success were often wanting in these operations. If an artery could be obliterated without dividing the inner coats, we were not justified in doing so. His own predilections were in favor of aseptic silk. He had had secondary hemorrhage with catgut. Chromic catgut had often produced a sinus lasting until its expulsion. Ox aorta tape he had used for the innominate, and had found that the vessel was not closed, but had a minute chink. It was hard to close a large vessel without using force enough to divide the inner coats. The tape was advantageous in vessels of next size to the innominate. To avoid disturbance of parts and to secure rapid union were important indications. Among the chief causes of secondary hemorrhage were suppuration, splitting of ligature, and disease of vessels

Surgeons should Prepare their Own Catgut.—MR. DAMER HARRISSON, of Liverpool, said that in twenty years' large hospital practice he had seen but one case of secondary hemorrhage after tying large arteries. The preparation of catgut was all important. If surgeons were to prepare their own catgut its use would be entirely justified. He personally quite believed in dividing the inner coats. Ox aorta could not be tied firmly enough for safety. In one case brought to him a surgeon had opened a popliteal aneurism in mistake for an abscess. By extending the wound he was able to tie the vessel by catgut ligatures. The result was successful, although the inner coats were not divided.

DR. H. O. MARCY, of Boston, Mass., said that for many years he had given special attention to the subject of ligatures. He had come to the conclusion that silk embedded in tissues was the best general suture. Catgut was entirely dependent on methods of preparation. Ordinary catgut in its first stage was a seething mass of corruption for days together. He agreed with the last speaker that every surgeon should prepare his own catgut. The fibres were arranged in a kind of lattice-work and not parallel to the long axis, an arrangement which did not afford the greatest amount of strength. He had grown a variety of bacteria from catgut taken from carbolized oil. In one case a myoma was ligatured with kangaroo tendon and healed perfectly, while the superficial wound, sewed with catgut, became septic. So long ago as 1827 Dr. Jamieson, of Baltimore, introduced an animal ligature, in the shape of the buckskin ligature of the native Indians.

DR T. C. PARKES, of Chicago, Ill., said that twenty years back he used silk for the femoral, and cure resulted. Now he used catgut, with equally good result. Success was dependent on the amount of pressure and the absence of suppuration. He agreed generally with what had been said by Mr. Holmes.

MR. T. H. BARTLEET, of Birmingham, said that secondary ligature after tying of large arteries was likely to occur less and less frequently under improved methods of treatment. Harrison Cripps mentioned ligature of external iliac only to condemn it. Erichsen recommended tying of bleeding-points. Aseptic sponges, as recommended by Mr. Jordan, were useful. In one case it succeeded where the axillary actually slipped out of sight. The depression in cases of secondary hemorrhage was quite out of proportion to the cause. He had ligatured the external iliac successfully, and deprecated the way in which that operation was condemned.

MR. T. HOLMES said that there was little to reply to, as his statement had been favorably received. He quoted a fatal case of secondary hemorrhage where the bleeding-points were tied, and in which amputation would have been the proper treatment. In a great number of cases ligature of the external iliac had proved unsuccessful. There were, however, cases of recovery on record where no treatment had been adopted.

Recovery after Abdominal Section.—MR. LAWSON TAIT, of Birmingham, showed several cases of recovery after abdominal section. In one a large papilloma of the ovary was removed. In others a large quantity of purulent fluid was evacuated, and the free discharge of caseous masses at the time (and subsequently) was followed by recovery.

Paraffin Casts of the Interior of the Kidney.—MR. JORDAN LLOYD, of Birmingham, showed a most interesting and original series of paraffin casts of the interior of the kidney. He maintained that the conceptions hitherto held of the so-called pelvis were erroneous. The casts were obtained by injecting paraffin into warm kidneys. Authorities described the kidney interior as a funnel-shaped bag, whereas in reality it was a series of tubes. This fact threw a new light on the surgery of renal calculus. There was no great skill required to remove a large renal calculus; it was the removal of small stones that was difficult and from which the best results were obtained. The ordinary teaching was that stone in the kidney was analogous to stone in the bladder; but in the kidney it was buried in solid tissues. Several ways had been suggested for finding the stone. Personally, he used the lumbar incision. There were the methods of palpation, puncture by needle, sounding. Bruce Clarke proposed incision of the lower part of the kidney to introduce the sound, and condemned digital exploration. Lawson Tait utterly condemned prodding the kidney with a skewer, and advocated finger exploration. By working the finger through the hilum, however, the whole of the system of secondary tubes could be explored. A double ureter might in this way be detected, a condition that would cause the greatest difficulty by ordinary plans.

MR. BRUCE CLARKE, of London, said that his own experiments had shown that exploration might best be effected by cutting through the kidney substance into the lower calyx. The plan of scratching through the hilum would endanger the vessels and other structures. In one case of sudden death after removal of a small stone, a clot had probably been dislodged from the vein.

Nerve-grafting.—MR. ATKINSON, of Leeds, read a paper on nerve-grafting. Five cases were narrated. The writer concluded that functional union took place rapidly in these cases; that healing by first intention, and even asepticism, did not appear to be absolutely indispensable in these cases; and that restoration of muscular movements was always delayed, sometimes long after sensation was established.

TENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Berlin, August 4, 5, 6, 7, 8, *and* 9, 1890.

(Special Report for the Medical Record.)

(Continued from page 188.)

SECTION ON SURGERY.

MONDAY, AUGUST 4TH, FIRST DAY.

Aseptic Surgery.—There was no regular meeting of the Section on this day, but the members assembled in the amphitheatre of the surgical clinic in Ziegelstrasse to listen to a lecture by Professor v. Bergmann on his aseptic (as opposed to antiseptic) method of operating. This method, he explained, is based upon the belief that wounds are seldom, if ever, infected through the medium of the air. The dust containing the noxious germs comes in contact with the open wound for a short time only, and, as a rule, gives rise to no infection. The walls of the operating-room should be smooth and easy to clean, and the floor is to be kept wet, so as to prevent the dust from rising. During an operation every precaution is taken to prevent the infection of wounds by contact. To this end—

1. The patient's skin is thoroughly disinfected at, and for some distance around, the place of operation. The skin is soaped and shaved, washed with soft glycerine

(potash) soap and sterilized water, and then rubbed dry with a sterilized towel. This rubbing should be done vigorously and carefully, in order to remove the superficial layers of epidermis, to which we find the impurities adhering which contain the infecting micro-organisms. After this the skin is washed with a solution of forty per cent. to fifty per cent. alcohol, and finally with a 1 to 2,000 sublimate solution.

2. In exactly the same manner the hands of the operator and his assistants are washed and made aseptic. The brushes which are used for this purpose are kept in a 1 to 2,000 sublimate solution, a precaution by no means superfluous, as bacteriological investigations have demonstrated the fact that great numbers of micro-organisms adhere to such brushes as are left exposed.

3. For each operation the patient is placed on a dry linen sheet, which has previously been sterilized, and is covered with similar sheets, so as to leave merely the region to be operated upon uncovered and freely accessible.

4. The instruments before use are boiled for five minutes in a one per cent. solution of carbonate of soda. In this solution they remain until required for the operation; then they are taken out, dried with a sterilized piece of gauze, and handed to the operator when he wants them. Whenever, in the course of the operation, they come in contact with anything not aseptic, all that is required to resterilize them is to dip them for a few seconds into the boiling solution of sodium-carbonate.

5. During the operation hemorrhage is most carefully controlled by means of pieces of gauze, which have been rendered aseptic shortly before. This gauze is not impregnated with any antiseptic agent, nor is it dipped into any antiseptic solution; but is pressed perfectly dry on the bleeding surface, and then discarded. All vessels are secured with torsion-forceps or Péan's forceps, and tied with catgut ligatures. The wound must be thoroughly dry and the hemorrhage completely stopped before the sutures are applied.

6. The catgut for ligatures is prepared from the commercial article by winding it in a single layer round a narrow glass slide and placing it in a five per cent. alcoholic sublimate solution. The silk for sutures is sterilized by steam.

7. The most essential condition for operating aseptically is the sterilizing of whatever the operator, assistants, or patient come into contact with. For this purpose all the towels, sheets, and surgeons' gowns, which are to be used for the operation, are, shortly before, placed in the sterilizing apparatus, where they are rendered aseptic by means of a current of steam. In this apparatus steam is allowed to pass from below through the contents, and the latter remain there for half an hour after they have arrived at the temperature of boiling water, so as so insure complete sterilization.

8. In exactly the same manner, and in the same apparatus, all dressing materials are rendered aseptic. The gauze is cut into pieces of the shape and size required for the dressings and for the operations in the clinic. These pieces, as well as all cotton-wool and bandages, are stuffed into bags, which are closed and put into the apparatus. There they remain until needed. Then they are taken out, opened, and their contents placed between aseptic sheets, and thus brought to the operating-table. The nurse who attends to this should also have previously disinfected her hands in the manner before described.

The speaker then applied the dressing in a case of carcinoma of the breast, which had just been operated upon by one of his assistants, and explained that such dressing would not be disturbed for eight days. He then removed the dressings in three other cases which had been operated upon a week previously. The wounds were in excellent condition, no suppuration having occurred. Other cases were shown in which suppuration had occurred before the operation was performed. One of these was a case of excision of the hip. The wound in this case would be stuffed with iodoform gauze, the speaker said, for two days, at the end of which time the gauze would be removed and the wound closed by sutures. Other similar cases of exsection of the hip were shown, in which the operation had been performed some time previously. In all of the older cases the wound had healed and the patients walked well without pain, though in all there was more or less shortening and also some flexion of the thigh. There was, apparently, some motion of the joint.

Congenital Dislocation of the Hip.—Two cases were then shown of congenital dislocation of the hip, one single and one double, wearing a specially devised apparatus, models of which were exhibited in the Exposition building. The children did not walk as well as patients with this deformity usually do without apparatus, and the braces were clumsy-looking, apparently difficult to fit to the case, and easily rendered ineffective.

Tuesday, August 5th, Second Day.

Professor v. Bardeleben opened the first session of the Surgical Section with a few words of welcome, in which he congratulated his fellow-members upon the enrolment of nearly one thousand names in the Section. He referred to the recent death of Volkmann, and called upon his hearers to rise in honor of his memory.

Surgical Osteogenesis.—Dr. Ollier, of Lyons, began the scientific work of the Section with a paper on this subject. He recalled the fact that Langenbeck, in 1859, had been the first to make practical use of the author's experiments in this direction by performing a periosteal rhinoplasty. He would divide the paper into two parts, treating first of subperiosteal resection and then of bone grafts.

Subperiosteal Resection.—There had been a sort of reaction of late against this operation, many surgeons having come to the belief that the results were unsatisfactory and in no way paying for the trouble of the operation. The speaker had performed more than five hundred resections and had had many opportunities in recent years to verify the results of these operations. In regard to the bones of the arm and forearm the new-formed osseous tissue took the shape essentially of the normal bone. The growth was principally in the direction of length, and in the case of the lower extremity of the humerus, at least, this was shown to take place chiefly by a compensatory hypertrophy of the epiphyseal cartilage. This occurs only when the member has regained its functions. It had been asserted that the newly formed bone would be reabsorbed, but the author's experience proved conclusively that this assertion was inexact. Volkmann thought that antiseptic dressings, by diminishing irritation, would interfere with the healing of fractures, but this fear was also shown to be unfounded. It has been claimed, also, that very extensive resections, such as are sometimes made in cases of tuberculosis, would interfere with the regeneration of new bone. This was the fact, and it was necessary, therefore, to remove only so much of the bone as was actually tuberculous, respecting the inflamed but not really diseased portions, as these were of great assistance in the process of regeneration of the osseous structure. The following were the results which he had obtained in the different joints: In the shoulder, always an enarthrodial joint; at the elbow the bone was reproduced with a shape very like the normal; in the wrist the results were less favorable because the carpal bones could not be reproduced; at the hip the results, in an orthopedic sense, were unsatisfactory; in the knee it is impossible to obtain a movable articulation, yet the author always practised subperiosteal resection here, as that was the best way of securing firm osseous union; in the case of the ankle he invariably removed the astragalus, obtaining thus a strong and movable joint.

Periosteal Grafts.—It has been conclusively shown by

autopsies and experiments upon animals that there is regeneration of bone as a result of periosteal and osseous grafts, but the new formation is not very pronounced. The author always preserved a thin layer of bone attached to the transplanted periosteum, and since adopting this practice he had obtained much more satisfactory results. As regards the use of bone plugs he thought the method was too recent to permit of its being judged correctly. In his experiments upon animals he had seen the pieces of bone disappear after a time. In some cases they seemed only to excite an irritation in the tissues, and under such circumstances he thought it would be preferable to employ pegs of ivory or platinum.

Tuberculous Ascites.—Dr. Koenig, of Göttingen, then read a paper on this subject. The disease was more common in women than in men, 16 only out of 137 cases which he had collected having been in the male subject. His treatment consisted in laparotomy followed by thorough lavage of the abdominal cavity with boiled water. Of 14 cases so treated by him, 7 were now in good health; 3 were dead from the original disease, the fatal result not having been hastened, however, by the operation; 1 died from collapse following the laparotomy, and 3 had been lost sight of. Among those operated on by other surgeons, the statistics of which he had been able to obtain, many were still in excellent health. One patient was still alive and well who had been operated upon by Sir Spencer Wells twenty-five years ago. Out of 131 operative cases which he had collected, 30 were alive two years after the operation, and 14 more than three years after. He did not admit as cured any cases in which life was not prolonged at least two years after the operation had been performed. As to the mode of cure, a comparison of statistics showed that it did not depend upon the kind of operative procedure employed, since all had given equally good results. The chances of a cure depend upon the extent to which the peritoneum is infected. This infection is ordinarily the consequence of tuberculous lesions of the intestine, and it is probably in those cases in which the changes in the mucous membrane are slight in extent, or already in process of healing, that a cure of the peritoneal disease takes place. After lavage of the peritoneal cavity further infection does not occur, and thus the cure is maintained. The remaining tubercles in the peritoneum are not removed by the lavage alone, but are gradually destroyed by the cicatricial contraction of the bands left after the operation.

The paper was discussed by Drs. Démosthène, of Bucharest, Subbotic, of Belgrade, and Kümmel, of Hamburg.

A Much-operated Patient.—Dr. Schuchardt, of Stettin, showed a young girl upon whom he had performed three operations within about a week for the relief of a typhlitic abscess. After the third operation the formation of pus within the abdominal cavity ceased, but still the fever continued, and it was then discovered that the girl was suffering from a pleurisy. Exploratory puncture showed the effusion to be serous, but containing many streptococci, so the speaker determined to perform resection of the ribs. This he did, and the patient recovered from the typhlitis, the pleurisy, and the four operations.

Treatment of Tubercular Peritonitis.—Dr. O'Callaghan, of Carlow, Ireland, presented a paper on this subject in which he advocated the thorough cleansing of the peritoneal cavity after laparotomy, giving the results in several cases of this nature which he had so treated. In the matter of a diagnosis he advocated a small exploratory incision, holding that the introduction of a finger would do no harm, and enabled one to arrive at a diagnosis much more easily and surely than could a simple puncture.

Treatment of Goitre.—Dr. Rossander, of Stockholm, presented a communication upon the experience of Swedish surgeons in extirpation of the thyroid gland for the relief of struma, an affection which occurred with tolerable frequency in his country. He advocated very strongly partial or complete extirpation of the thyroid gland, in spite of the assertion of physiologists concerning the vital importance of that organ. In the first place, he argued, it is not always allowable to reason from the lower animals to man, and what may be of supreme importance to a dog may possibly be easily dispensed with by man; and in the second place, the functions of the excised gland may in great measure be performed by the spleen. He would, however, advise the surgeon to proceed cautiously, removing only a portion of the gland at first. But if this did not suffice for a cure, he would without hesitation extirpate the entire organ.

Scrotal Tumor and Other Troubles.—Dr. Bockenheimer, of Frankfort, presented the photograph of a man, forty five years of age, who was born with a flat foot, and later acquired elephantiasis. After this, lateral curvature of the spine appeared, and became so marked that the patient walked bent, laterally, almost to a right angle. Finally there came in the place of the scrotum a tumor, twenty inches in length, the external appearance of which resembled in no respect the integument of the scrotum. It was impossible to remove this tumor, and the only treatment for it had been the construction of a suspensory bandage.

Wednesday, August 6th, Third Day.

Surgical Treatment of Intussusception.—Mr. Jonathan Hutchinson, of London, read a paper on this subject, in which he advocated laparotomy and the drawing out of the intussusception by means of a long tube made of glass and caoutchouc. He had treated a number of cases in this way with a large percentage of successes.

Mr. Howard Marsh, of London, called attention to the great danger of collapse, after laparotomy, in children, and urged the necessity of caution on that account.

Resection of the Stomach and Intestines.—Dr. Billroth, of Vienna, presented the statistics of all the cases of resection of the stomach and intestines performed in his clinic in the years 1878–90. He excluded those cases in which operation was necessitated by gangrene of the intestine, and presented only those in which resection was performed for the removal of intestinal tumors or for the relief of stenosis of the pylorus. There were in all 124 cases, of which the author himself had performed 83, the rest having been done by his assistants. Forty-one of the total number were resections of the pylorus, and of these 28 were for carcinoma and 1 for sarcoma. The time required for the operation varied between one and three-fourths and three and one-half hours. The excised pieces varied in length from 4 to 21 ctm. Of 27 cases of typical pyloric resection, 15 died and 12 recovered; and of the entire 41 cases there were 19 recoveries and 22 deaths. A number of those who recovered died from return of the disease at the end of from one to eleven years. Four of the cases were still alive, two of whom, at the end of one and five years, respectively, seemed to be entirely free from any return of the disease. There were several cases in which there was no stenosis, but merely a sharp bend at the pylorus; three of these, in which it had been very difficult to detect the bend, ended fatally, one from collapse and two from peritonitis, the latter probably in consequence of defective antiseptic treatment.

Enterotomy.—There were 28 gastro-enterotomies performed, fifty per cent. of which recovered. Of 11 patients upon whom resection of the small intestine was performed, all recovered. Of 24 cases of operation on the cæcum 11 died; and of these 24 cases there were 11 of carcinoma, 6 of whom died and 5 recovered. There were 8 cases of operation upon the colon, of which 4 recovered; two of the operations were for fecal fistula, one of which resulted fatally. Collapse was the cause of death in 6 out of the 22 fatal cases of pylorectomy, and

in 9 of the 14 deaths after gastro-enterotomy, although the former operation takes much more time than the latter. This was explained by the author by the fact that gastro-enterotomy is more often performed in persons who are already in a low condition. In regard to sutures it is well not to make them too deep for fear of causing gangrene of the intestinal wall. It has been objected against this class of operations that the probability of a complete recovery is too slight to weigh against the great danger of the operation. In reply to this Dr. Billroth held that a radical cure of carcinoma occurring in other parts of the body was seldom obtained, and that the average time before a return of the disease took place was as long here as when the neoplasm was found in other parts, and yet no one hesitated to operate in the latter case. The danger of operations on the intestinal tract lay in the technique; but the author believed that in time we should be able to overcome these dangers, and that then it would be no more hazardous to operate for carcinoma in the stomach and intestines than it is now to remove the neoplasm affecting other parts of the body.

Dr. Postempski, of Rome, related two cases in which he had performed gastrotomy; one of these, occurring in a boy of ten years, resulted favorably, while the other, in an old woman suffering from carcinoma, terminated fatally.

Dr. Novaro, of Sienna, reported ten cases of pylorectomy and eleven of gastrotomy. His experience led him to favor the Wölfler method of operating.

Dr. Lauenstein, of Hamburg, presented the statistics of twenty-five cases of resection of the stomach performed by him, twelve of which were for the relief of pyloric stenosis. He insisted especially upon the necessity of a strict observance of every possible antiseptic precaution.

The Technique of Resection of the Stomach.—Dr. Knie, of Warsaw, read a paper on this subject. The vitality of the mucous membrane of the stomach and intestine depends upon the circulation in the outer layers, and therefore he recommended that special measures be taken to prevent a cutting off of the circulation in the serosa and musculosa.

Dr. Bernays, of St. Louis, said that he had had several cases of gastrotomy after the Wölfler and Hacker methods, but the patients did badly, although the fatal result could not be attributed directly to the effects of the operation. He then adopted a method of operating which is used to some extent in England, but is practically unknown as yet in Germany. This consists in making a very small opening in the anterior wall of the stomach, through which the finger is introduced and as much of the diseased part removed as possible, the rest being scraped away with the sharp spoon. He reported a case of a tumor as large as a cocoa-nut which he removed successfully in this way. The tumor weighed a pound and a half, and was removed through an opening only two and a half inches in length. The author believed that Billroth's operation of resection of the stomach might render good service in individual cases, but he thought too much reliance should not be placed upon it.

Dr. Mayot, of Antwerp, referred to the statistics of a number of cases of resection of the stomach performed by himself. Of upward of 80 cases of intestinal operations that he had performed, there were 30 cases of resection, the balance being operations for closing of fistulæ. Of these 30 cases 9 were resections of the colon, 3 having been operated upon more than once. The speaker advised a double row of sutures, one through the mucosa and the other through the muscular coat. He was in accord with the plan approved also by v. Volkmann, of not resorting at once to a resection in cases of carcinoma of the intestine. He would first make an artificial anus, and later, if no return of the disease took place, close the opening and perform a resection of the gut.

Dr. Koenig, of Göttingen, hoped that there were few members of the Section in accord with Dr. Bernays in condemning Billroth's operation, an operation which he regarded as marking one of the greatest advances of recent times. The sharp spoon was of value in former times before the operative technique had reached its present stage; but it was now, or ought to be, obsolete. No one should ever, at the present day, treat any neoplasm, whether it were in the skin, the stomach, or intestine, with the sharp spoon.

An Improved Wölfler Operation.—Dr. Wölfler, of Gratz, reported a modification which he had been led to make in his operation. He no longer united simply the under wall of the stomach with the duodenum, but turned the latter round in a curve before uniting it to the stomach. In this way he maintained that the peristaltic action of the stomach and duodenum coincided in direction, whereas, in the former method, two peristaltic waves running in opposite directions met at the point of union of the viscera.

Thursday, August 7th, Fourth Day.

Prostatic Hypertrophy.—Dr. Enrico Bottini, of Pavia, described the method for relief of this condition, which he had first published in 1877, and had since modified and improved. There were two distinct operations, according as the object was to remove wholly the enlargement, or simply to cut a grove for the passage of the urine. The first is effected by means of a galvano-cautery of such strength that the entire operation can be done within a few minutes at a single sitting. The author now uses a storage battery, charged from a dynamo, which is powerful enough to raise pieces of platinum of considerable size to a red or white heat almost instantly. The cauterizing apparatus resembles a Mercier's sound somewhat. It consists of four parallel tubes, two of which are for the wires, and the other two for the purpose of conducting a stream of water to keep the instrument cool. The cautery proper consists of a **U**-shaped ribbon of platinum passing over a small porcelain cylinder, which serves at the same time for a support and to retain the heat. The instrument is introduced into the bladder and then withdrawn, so that the cautery rests against the third lobe of the prostate. The electrical current is then turned on, and the gland is burned. Often the burning tissues can plainly be heard sizzling. The patients do not complain of any severe pain during the operation. Care must be taken on withdrawing the instrument not to tear away the eschar, as there is then some danger of hemorrhage.

The incisor apparatus resembles Mercier's instrument, except that the cutting part is of platinum instead of steel. The operation consists in three parts, namely, introduction, incision, and withdrawal. The introduction is effected in the usual way, then the current is turned on and the knife pressed against the tissue to be cut through. When the sound of the burning tissue is plainly heard the knife is to be moved gently back and forth until the projecting lobe is thoroughly divided. Then the knife is concealed in its sheath, the instrument pushed forward into the bladder to insure that it is not caught anywhere, and then withdrawn. As to a choice between the two operations, the author thought that the total destruction of the obstructing lobe was advisable when the hypertrophy is not very great, but that in advanced cases it would be better to cut through it. Either operation would be contra-indicated when kidney disease was present, or even suspected. Dr. Bottini had operated after this method on 57 cases, 2 of which had resulted fatally; these, however, were during the early days of the operation, before the instruments had been brought to their present state of perfection. In 32 cases a perfect cure had been obtained, in 11 there was an improvement, and in only 12 was no benefit observed. These results in the case of an affection which was so rebellious to ordinary treatment were a powerful argument in favor of the method, and the author hoped soon to see it adopted more generally by surgeons than it had yet been.

MR. MCGILL, of Leeds, said that it was necessary to work here in the dark, and he thought therefore that the operation was inferior to cystotomy, the results of which under improved technique were now extremely favorable.

MR. BRUCE CLARK, of London, had been much interested in Bottini's method. One operation of this kind in his hands had resulted successfully, but others, performed later, had failed. The cause of the failure was that changes had occurred in the hypertrophied gland which it had been impossible to discover. In order to know with certainty what has taken place in the bladder a cystotomy is necessary. In many cases, however, in which one thinks that he has to do with an hypertrophied prostate, the gland is simply inflamed, and will return to its normal size in a short time without any further treatment.

Lateral Prostatotomy.—DR. KUESTER, of Berlin, called attention to the operation of lateral prostatotomy, which had been proposed by Dittel, but had been tried by him only on the cadaver. The speaker had operated in this way twice on the living subject, in cases in which the lateral lobes of the prostate gland were enlarged. In both instances the operation was very successful. In one case the urethra was accidentally wounded, but the resulting fistula healed kindly.

A New Operation for Cancer of the Rectum.—DR. AXEL IVERSEN, of Copenhagen, then presented a communication on this subject. One can never know with certainty whether the disease is limited to the rectum or whether the neighboring glands are also involved, and it is therefore difficult to settle the question as to whether an operation is indicated. Colotomy will relieve for a certain time, and often indeed for a long time, the symptoms dependent upon the coprostasis, but it does not help the pain nor reduce the fetid secretion. The want of a more radical operation for the relief of this terrible disease is therefore still urgently felt. It is known that cancer of the rectum often remains stationary for a long period, and the author had made autopsies on 47 long-standing cases of cancer of the rectum, in 21 of which there had been no metastasis. This fact gives hope of success from a radical operation. In judging of the latter we need not consider the direct mortality so much as the tendency to a return of the disease. The author then presented some statistics of 247 cases of operation for rectal cancer performed in the Scandinavian countries, which showed only a very small number of patients who had survived the operation for several years without having had a local relapse. The results of extirpation were slightly better, as regards prolongation of life, than those of colotomy, but they were little or no better in respect to relief from pain. The author then spoke of the different methods at present in favor, showing wherein they were defective. He thought too great an effort had been made to preserve continence of fæces, and the operations had therefore not been radical enough. The surgeon should not hope for too much—the essential thing is to make the operation a radical one. A partial operation should be undertaken only when the disease is strictly limited to the anus. In every other case, if one is to operate at all, it is necessary to perform total extirpation of the rectum, making a permanent artificial anus in the sacral region. Unless this is done it will be impossible to remove all the glands which are liable to be infected. The extirpation of the tissues surrounding the intestine is also necessary, as here are often located the "seedling" cancers (*cancers semés*). The operation is performed as follows: After a preliminary Kraske operation, with or without resection of the sacrum, oval incisions are made surrounding the anus and then the rectum is dissected out from below upward, care having been taken to tie a ligature around the anus in order to prevent the escape of the contents of the gut. All the presacral connective and adipose tissue is then removed. Next the peritoneum is opened and the intestine drawn down. Now the intestine and the parietal layer of the peritoneum are stitched together, and the cavity remaining after the operation is stuffed with iodoform gauze and drawn together by stitches. The author had operated in this way on six cases, four of which had resulted fatally.

MR. BRYANT, of London, was led, from his own experience, to oppose the operation of excision of the rectum, on account of the great mortality following it, and preferred colotomy with the formation of an artificial anus. This was the practice of most English surgeons.

DR. LANGE, of New York, spoke of the advantage of placing the patient upon the abdomen during this operation, as thereby the fluids were prevented from running into the peritoneal cavity. He had obtained good results from a plastic operation, by means of which the patients are enabled to retain the solid, and even fluid, contents of the intestine, though not always gases.

DR. KÖNIG, of Göttingen, had formerly regarded the prognosis of resection of the rectum as very unfavorable, but since adopting v. Bergmann's method had obtained much more favorable results. He preferred the high operation.

DR. CZERNY, of Heidelberg, thought that with improved technique the results of the operation would become much better. He thought the inguinal region preferable to the lumbar for the location of the artificial anus.

Operations on the Lateral Ventricles.—DR. W. W. KEEN, of Philadelphia, then read a paper on the operations performed by him in opening the lateral ventricles of the brain, explaining the mode of performance and the results obtained.

FRIDAY, AUGUST 8TH, FIFTH DAY.

Diagnosis of Shot-wounds of the Stomach and Intestine.—DR. N. SENN, of Milwaukee, gave a demonstration of his method of diagnosis of shot-wounds of the intestines by means of the injection into the rectum of hydrogen gas.

Laparotomy for Shot-wound of the Abdomen. — DR. BERNAYS, of St. Louis, reported a case of accidental shot-wound of the abdomen where a pistol-ball had perforated the stomach, liver, diaphragm, and pleura, in which he had performed a laparotomy, stitching up the stomach-wounds. The patient made a good recovery.

Vesical Calculus in Russia.—DR. LEVSHIN, of Kazan, presented numerous statistics relative to the frequency of stone in the bladder in Russia. He had collected upward of sixty thousand cases. Most of the cases occurred in young individuals. He had been unable to come to any satisfactory conclusion concerning the etiology of the disease.

DR. KUSMIN, of St. Petersburg, had seen a great number of cases of this affection in young children.

DR. ARETÆUS, of Athens, said the disease was very prevalent in Greece, and he alone had operated on 256 cases, of which 99 were in children under ten years of age. In 20 of the cases the stone was in the urethra.

DR. POIRIER, of Paris, read a paper on the "Pathogenesis of Cysts of the Knee," in which he said that these cysts could arise from disease of the upper parts of the leg as well as from that of the lower parts of the thigh.

DR. LANGE, of New York, presented a new needle-holder, in which the needle was held much more firmly than in the ordinary instruments.

The Production of Artificial Hernia.—DR. BORNHAUPT, of Kief, read a paper upon the production of artificial hernia by men who wished to evade military service. Among certain classes of Russian subjects the aversion to service in the army is so great that the men will resort to almost anything that will secure them exemption. It is said that cataract is not infrequently produced to this end, and lately a number of men in a single regiment, all coming from the same portion of the country, were found to be suffering from hernia, which was supposed to have been artificially brought about by means

of an instrument shaped something like a glove-stretcher. These hernias were all situated on the left side, and it was thought that the instrument causing them was introduced into the rectum. It had, however, as yet been impossible to learn exactly how these injuries were produced.

DR. MARCY, of Boston, then demonstrated the sutures used by him, which were made out of kangaroo gut.

Treatment of Stricture by Linear Electrolysis.—DR. LEON LE FORT, of Paris, read a paper describing his method of treating strictures of the urethra, rectum, and œsophagus by means of linear electrolysis. Of seven hundred cases of urethral stricture so treated he had had not a single failure. The operation was largely practised in France and Italy, and had lately been extended to the treatment of strictures of the rectum and of the œsophagus.

DR. KOLLMANN, of Leipsic, showed a number of photographs of the urethra which he had made with the Nitze-Oberländer electro-cystoscope.

MR. WEEKS, of London, presented some drainage-tubes made out of sections of arteries, which he had used and found preferable to rubber tubes because of the fact that they were readily absorbed.

Surgical Tuberculosis.—DR. BIONDI, of Bologna, read a paper on this subject, in which he maintained that there were two varieties of tuberculosis, one characterized by multiplicity and activity of the lesions, the other by a local lesion running a rapid and favorable course. The disease can be propagated in other animals by inoculation with bacilli taken from the first variety, but not by those taken from the other. The author suggested that possibly the second variety was related to the tuberculosis of chickens, which is known to differ widely from that found in mammals.

Exstrophy of the Bladder.—DR. SCHMIDT, of Heidelberg, showed some drawings and a model taken from a case of exstrophy of the bladder, upon which Dr. Czerny had performed a plastic operation with complete success.

A number of other papers were read, instruments shown, etc.

The different meetings of the Section were presided over by Drs. Bardeleben, Le Fort, Lister, Ollier, Novaro, Parkes, Rossander, Skliffosovski, Aretæus, and Rugio, and Prince Carl Theodor, of Bavaria.

ECHOES FROM THE CONGRESS.

The Reception in the Rathhaus was perhaps the most memorable incident of the Congress: certainly it will never be forgotten by those who took part in it. Not only the large hall, but nearly every other room in the entire building was thrown open to the guests. Tables were everywhere, and buffets loaded with solid and liquid refreshment were nearly as numerous. Wine was to be had for the asking and even without asking, and the spirits of the guests rose rapidly. There was, however, notwithstanding the general hilarity, the utmost good nature and good order everywhere.

An Exhibition Drill of the Fire Department was on the programme for Wednesday morning at half past eight o'clock. Punctually at that time the fire-engines with their crews were at the appointed place, where they waited until eleven o'clock, but no doctors appeared to witness the drill, as the Secretary-General of the Congress had forgotten to give notice of the exhibition.

The Three Largest Sections of the Congress were those of Internal Medicine, Gynecology, and Surgery. The latter numbered between 800 and 900 members.

"**The Journal**" of the Congress which appeared each morning was edited by Dr. S. Guttmann. The task was no light one, but the undertaking was very successful, thanks to the labors of the learned editor.

Unter den Linden was the cause of much disappointment to the foreign members of the Congress. The street is very wide and lined with cafés, hotels, and fine shops, but the linden trees are small and of uneven size, and look like mere bushes in comparison with the elms and other stately trees to which American eyes are accustomed.

An International Congress of Cremation Societies was held in Berlin August 4th, 5th, and 6th. An invitation was extended to the members of the Medical Congress to be present at their sessions, but was not very largely responded to.

Excursion to Havel Lakes.—One of the most enjoyable excursions was that given by the Berlin Laryngological Society to the Laryngological Section. The members were taken a short distance by rail to the shores of the Havel Lakes, where they embarked on a steamer and sailed for a couple of hours through those beautiful waters. Although unlimited refreshments were served on the boat, soon after landing near Potsdam the guests sat down to a dinner in the open air. Here many toasts were drank and numerous complimentary speeches made. At a seasonable hour in the evening the party was brought back to Berlin.

The Weather.—Those who believed they were going to a northern land where the days were never oppressively hot and the nights always cool were grievously disappointed in their expectations. Up to the very last day of the Congress the heat was excessive, and the sufferings of those taking part in the general or section meetings were very great. The atmosphere in the Circus Renz especially, at the time of the first general meeting, was absolutely frightful. The day was warm, the hall was packed to suffocation, numerous gas-lights did their part in consuming the oxygen, and then there was not the slightest provision for ventilation. The Exposition Building, where the sections met, resembles very much an enormous hot-house, but it is so large that the lack of provision for ventilation was somewhat less noticeable here than in the Circus Building. The Congress was fortunate, however, in the fact that rain fell but once during the week, and that late at night, so there was no interference with going about during the day or with the open air festivities in the evening.

Attendance.—The Berlin Congress will probably for a long time be remarkable among the others for the very large number of registered members. The total number was 5,737, distributed among the different nations as follows: Berlin, 1,166; Germany, outside of Berlin, 1,752; Austria-Hungary, 262; Great Britain and Ireland, 358; Holland, 112; Belgium, 62; Luxembourg, 2; France, 179; Switzerland, 67; Italy, 146; Monaco, 1; Spain, 41; Portugal, 5; Sweden, 108; Norway, 57; Denmark, 139; Russia, 429; Turkey, 12; Greece, 5; Roumania, 32; Servia, 2; Bulgaria, 5; United States, 659; Canada, 24; Brazil, 12; Chili, 14; Mexico, 7; other countries of America, 30; Egypt, 8; Cape Colony, 1; other parts of Africa, 5; China, 2; Japan, 22; East Indies, 2; Dutch East Indies, 2; Australia, 7;

Dr. Rudolph Virchow, President of the Committee on Organization, was a grand success; the Secretary-General was not.

The Ladies' Reception Committee.—A committee, composed of the wives of some of the Berlin physicians, was formed for the purpose of entertaining the wives and daughters of the visiting members. Some of them were always to be found in the statuary hall of the Exposition Building. Their services were most graciously rendered and were gratefully appreciated by the lady guests. Under their guidance the visitors saw many of the sights of the city and visited many of the charitable institutions.

"**Festgaben.**"—To each of the members of the Congress was presented two or three large bound volumes

containing a fdll description of all the hospitals, clinics, asylums, charitable institutions, both public and private, sanitary works, laws relating to hygiene, etc., in Germany. Indəed, one became a little tired of hearing so much about the remarkable progress in matters of hygiene and sanitation in the German Empire, and especially in Ber lin. The presidential address was largely devoted to a review of such works in Berlin; excursions to the water-works, sewage-farms, slaughter-houses, and other similar places were planned for nearly every day during the sessions of the Congress; the books above referred to were distributed gratuitously to the members, and yet, in the practical and eminently hygienic matter of ventilation there was a lamentable deficiency. Not only in the places of meeting, where the atmosphere was hot and insuffer ably close, but elsewhere in Berlin was this most notice-able. Even in the street-cars the windows and doors were kept tightly closed, and the conductor's chief end seemed to be to prevent the admission of any fresh air to the interior of the vehicle. Yet the passengers appeared to like it.

Extracts from the Journal.—*Lost.* A member on the occasion of the Reception in the Rathhaus has lost a large brilliant ring of the value of 3,000 marks. It is requested that the finder should return the same to the Bureau of the Congress (Ausstellungspark).

A member of the Congress who lay from 11 to 2.30 in a state of unconsciousness at the Rathhaus on Tuesday evening, and who was attended by several confrères who injected ether, requests the gentlemen who accompanied him to his house to leave their name and address in the Bureau of the Congress.

During the reception in the Rathhaus one of the guests has taken his Gibus for mine. He is begged to return it to the following address.

One Result of the Congress was stated by a Berlin newspaper to have been the publication of four hundred engagements of marriage. Evidently Science was not the only attraction drawing the two thousand German strangers to the imperial city.

Sudden Death Illustrated.—Among other objects in the medico-scientific exhibition were several preparations illustrating some of the modes of accidental death. One specimen was that of a man who made a wager that he could swallow a beefsteak whole. He died in consequence of the attempt, and the preparation showed the meat still sticking in his throat. Another was that of a woman who suddenly fell down in the street, and died before medical assistance could be obtained. Her false teeth had become dislodged and choked her. In another specimen illustrating sudden death from asphyxia the accident was shown to have been caused by a quid of chewing tobacco in the larynx. Several skulls crossed in all directions by numerous red lines had been taken from men killed by falling from a height. Comminuted fracture had occurred, and the red streaks showed the lines of union where the various pieces had been cemented together. Other skulls showing bullet-wounds were to be seen, and one was exhibited with an axe firmly driven through the bone where it had been implanted by the wife of the victim.

The English Programme was for some reason delayed in its publication, not appearing until the day after the opening of the Congress.

The Streets of Berlin compare very favorably, in the matter of cleanliness, with those in most American cities. This is in large measure to be attributed to the fact that many of them are paved with asphalt, and can thus be easily swept by the gangs of street-cleaners. These latter are armd with rubber scrapers and follow the watering-carts, gathering all the mud and manure into little heaps along the curb, which are then carted away before they have had time to dry and be spread again over the street.

THE TENTH INTERNATIONAL MEDICAL CONGRESS FROM AN AMERICAN POINT OF VIEW.

To the Editor of the Medical Record.

Sir: The Tenth International Congress is finished and most of its six thousand members have gone away. The impressions made as regards its success are various and depend somewhat upon the personal experiences of the visitors. On one point all are agreed: the social part of the meeting was carefully arranged and carried out to the immense satisfaction and enjoyment of everyone. The municipality and the physicians of Berlin lavished their money and time in providing dinners, balls, excursions, and the humbler social reunions for their guests. Perhaps the most notable entertainment ever given in the history of medicine was the grand banquet at the new Rathhaus (Town Hall) Tuesday evening. It was necessary to provide for the simultaneous feeding of four or five thousand men and it was successfully done. The Rathhaus is a beautiful building, with large halls and broad corridors, all of which were filled with tables. These were loaded with viands and dark with bottles of wine. The affair began at nine and five minutes later the tables were nearly full and three or four thousand doctors were hard at work. The wine was supplied without stint and it was the opportunity of a life to our German confrères. They eat and they drank; then they drank, and finally they drank again. A general feeling of exhilaration gradually came upon all; they laughed, they talked, they sang, they embraced, they clinked their glasses; eternal amity was sworn, bald heads were baptized in excess of warm champagne. By twelve o'clock the three big halls, the corridors, the staircases, and all the smaller rooms were filled with a joyful panorama illustrating the gayety of nations. The band played, the men of science sang, and toasted all the tribes of the earth. Some such colossal scenes may have occurred among the gods of old Olympus, but never before at a meeting held in the interests of science. The learned men went home that night and felt that the world was advancing and that the great municipality of Berlin was at its head.

The Section dinners went off more quietly. The great ball had to be divided into five parts, but each of the parts was well attended, well organized, and greatly enjoyed.

The parting feast on Saturday night came off at Kroll's Garten. This is a higher class of beer garden with a theatre connected with it—a charming place withal. A concert was given in the theatre while beer flowed freely in the Garden, as it always does in Berlin. By twelve o'clock, the assemblage was ready for a speech and Virchow made one, after which, amid many "hochs" as well as American cheers, the old gentleman was lifted up and carried around in triumph.

We all felt that too much praise could not be given to the physicians of Berlin for their courtesies to their guests.

Leaving this, however, and turning to the scientific side of the Congress, we have a very different story to tell. The Section organization was wretched and in many cases came as near being a failure as was well possible. The German does not in the least understand how to organize medical meetings. No lists of members were furnished, the announcements of papers to be read were most imperfect and incomplete, and many found that they could get no chance to read at all. America was well represented in most sections, but anyone who spoke English received scant attention, while the Germans would read and talk almost indefinitely.

In the Surgical Section a little stir was made by the paper and demonstrations of a Berlin surgeon, who excises joints, puts in ivory joints in place of those removed, and, as he claims, secures healing with motion and fairly useful limbs. He showed on a skeleton his various forms of ivory joints for the knee, ankle, wrist, etc. The comments on the method, however, were very unfavorable and severe.

Mr. Horsley made a most favorable impression by his paper on the surgery of the brain, and by his demonstration of the cortical centres for the larynx. In the Laryngological Section one of the best papers was by a Brooklyn physician, Dr. French, on the physiology of the singing voice.

Dr. Andrew H. Smith's address in the Section on Internal Medicine was well spoken of, and Dr. H. C. Wood's address on "Anæsthesia," at the general meetings, also received many encomiums. In fact, so far as they had or took opportunity, the Americans did creditable work.

In the Ophthalmological Section some interesting discussions took place upon refractive errors, and the doctrine was promulgated that if these errors are properly corrected there will be no muscular asthenopia.

In the general meetings, of which there were only three, set addresses were given, and of these you have already published abstracts. The Germans are advanced in some things, but they have no idea of ventilating their public buildings (they prefer to sit and perspire), and the Renz Circus, where the general sessions were held, would make a total obscuration of the Black Hole of Calcutta if it were given half a chance. Still we all did penance there at least once.

The meetings of the Sections were held in a large, rambling, glass structure devoted to the annual exhibition of new and modern paintings. It is, I take it, the "Salon" of Berlin, but if so, Berlin is very far from being an art centre. This exhibition was closed for a week, so that the Congress could use the rooms. This was very kind and it was doubtless the best that could be done; but the rooms were large, high, and only partly enclosed, so that it was very difficult to hear the speakers—a fact which interfered greatly with successful discussions in many cases.

The exhibition held in connection with the Congress was a most extensive and interesting one. The collections of surgical instruments, of instruments of precision of all kinds, the balneological, pharmacological, pathological, microscopical, electrical, and other exhibits, afforded a most interesting opportunity for study. It was far in advance of previous displays of this kind.

America naturally was hardly represented at all, for our manufacturers get no market in Europe. In many departments of instrument making, however, we are in advance of the German manufacturers.

In estimating the value of such congresses as we have just had one must at once admit that it does not lie in new discoveries announced, or new ideas evolved, or great original work presented. It lies rather in meeting with co-workers from other lands, in forming pleasant associations with these, and obtaining opportunity to exchange informally and freely opinions upon work in which there is a common interest. Such meetings serve to broaden the science of medicine, to prevent dogmatism, and to pour into the common stock those established facts and those rational methods which make the basis of our art.

M.D.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 17 to August 23, 1890.

KENDALL, WILLIAM P., First Lieutenant and Assistant Surgeon. To be assistant surgeon with rank of captain (after five years' service), from August 12, 1890. Headquarters of the Army, A. G. O., Washington, D. C., August 18, 1890.

IVES, FRANCIS J., Assistant Surgeon. To be assistant surgeon with the rank of captain (July 25, 1890), after five years' service, in accordance with the Act of June 23, 1874. Headquarters of the Army, A. G. O., Washington, D. C., August 11, 1890.

REED, WALTER, Captain and Assistant Surgeon. With the approval of the Acting Secretary of War, granted leave of absence for four months, to take effect about September 1, 1890. S. O. 192, par. 17, A. G. O., Washington, D. C., August 8, 1890.

MIDDLETON, JOSEPH V. D., Major and Surgeon; EWEN, CLARENCE, Major and Surgeon; and HOPKINS, WILLIAM E., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, will assemble at the United States Military Academy, West Point, N. Y., at 11 A.M., August 27, 1890, or as soon thereafter as practicable, as a board of medical officers, to examine into the physical qualifications of the candidates for admission to the Academy. S. O. 192, par. 1, A. G. O., Washington, D. C., August 18, 1890.

MASON, CHARLES F., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War, relieved from further temporary duty at Fort Logan, Col., and will report for duty at his proper station (Fort Washakie, Wyo. Terr.). S. O. 191, par. 3, A. G. O., Washington, D. C., August 16, 1890.

MOORE, JOHN, Brigadier General and Surgeon-General. By direction of the Acting Secretary of War, retirement from active service this date by operation of law, under the provisions of the Act of Congress approved June 30, 1882, is announced. General Moore will repair to his home, Bloomington, Ind. S. O., 191, par. 2, A. G. O., Washington, D. C., August 16, 1890.

MCCREERY, GEORGE, Captain and Assistant Surgeon. The leave of absence for seven days granted by orders No. 84, Fort Warren, Mass., August 13, 1890, is hereby extended fifteen days. S. O. 193, Headquarters Division of the Atlantic, Governor's Island, New York City, August 15, 1890.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 23, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	37	12
Scarlet fever	12	4
Cerebro-spinal meningitis	1	2
Measles	81	12
Diphtheria	39	14
Small-pox	0	0
Varicella	0	0
Pertussis	5	16

Lead-water and Cantharides.—Dr. Pied writes, in the *Gazette Médicale de Nantes*, that it is impossible to raise a blister by applications of Spanish fly to parts which have been bathed in lead-water. The reason of this is probably that a chemical reaction occurs, an insoluble cantharidate of lead being formed. When it is desired to blister a part upon which lead lotion has been used, it is necessary to scrub the skin thoroughly with soap and water, or to apply first some other substance, such as tincture of iodine, which will combine with all the oxide of lead present upon the surface.

The Use of Buttermilk in Vomiting.—Dr. Stanley M. Ward writes in the *Therapeutic Gazette* that he has found fresh buttermilk very serviceable in relieving vomiting of various forms, even at times the vomiting of pregnancy. The remedy is administered ice cold, in doses of about half a teaspoonful repeated every fifteen or twenty minutes. In the case of children with cholera infantum he has often succeeded in quieting the stomach by interdicting everything else and using a few drops of fresh ice-cold buttermilk at intervals varying in length according to the severity of the case.

THE TREATMENT OF PERTUSSIS BY BROMOFORM.

BY LOUIS FISCHER, M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLIKLINIK, NEW YORK.

BROMOFORM, $CHBr_3$, is a colorless liquid, boiling at 151° C., and solidifying at 2.5° C. Its specific gravity is 2.83 at 0° C. It is produced by the action of bromine upon alcohol in the presence of an alkali. In practice milk of lime is saturated with bromine, alcohol added, and the mixture distilled. In 1849 Nunneley and Schuchard called attention to bromoform as a possible anæsthetic, and in 1869 Rabuteau[1] brought the drug forward as a new anæsthetic.

Given to the lower animals by inhalation or hypodermic injection bromoform produces rapid narcosis, in which, according to the researches of Von Horoch,[2] the breathing is not noticeably lessened and the pulse remains full, regular, and strong. Although the blood-pressure is distinctly reduced, the heart is said not to suffer from the influence of the drug, and the peripheral vagi are not affected. Further, as powerful irritation of a sensory nerve has no influence upon the blood-pressure, it is probable that the fall is the result of vaso-motor paralysis, which is confirmed by the rapid sinking of the temperature.

The excitability of the cerebral psycho-motor centres and the general reflexes are entirely destroyed. Von Horoch has used the bromoform as an anæsthetic in several cases in man. The most marked symptom was excessive cyanosis of the face. The urine passed after recovery contained bromine.

More recently Dr. Stepp, of Nuremberg, applied bromoform successfully in the treatment of whooping-cough, and still more recently Professor Senator, through his assistant, Dr. Loewenthal, of Berlin, published an article in the *Berliner klinische Wochenschrift*,[3] heartily endorsing Dr. Stepp's treatment and recommending its further use, promising to again publish his results.

He noticed in some cases a decided benefit as early as the second day of treatment, in others on the third or fourth day, depending on the severity of the case.

Vomiting disappeared in the first week of the bromoform treatment. Bronchitis, complicating tussis convulsiva, seemed to be benefited also during the course of the treatment. In from two to four weeks children were usually discharged cured. Appetite also was better during the course of treatment. Children with previous morbilli, also delicate ones, experienced equally beneficial results. Some cases had the treatment interrupted by a complication setting in, *e.g.*, morbilli, pneumonia, or varicella. Relapses occurred where bromoform was not administered long enough; in some cases sleepiness was observed during the course of treatment. In a case where a toxic dose of $CHBr_3$ was given, the following symptoms were noted: Contracted, pin-point pupils; small, compressible pulse; pale countenance; cornea not reacting; on auscultation long deep inspiration; hardly any expiration was noticed; the heart-sounds were scarcely perceptible. The child reacted immediately on giving a hypodermic injection of sulphuric ether.

[1] Gaz. Hebdom. de Méd. [2] Wiener Mediz. Jahrbuch, 1883.
[3] June 9, 1890.

The following cases will illustrate the manner in which I have applied bromoform, and show the results:

CASE I.—R. G——, two years of age. Has had pertussis fifteen days; daily average ten to eighteen attacks of coughing. Treatment commenced with two drops three times a day after meals. After giving twenty drops child had only two or three attacks of coughing in twelve hours. In this case the child received in all forty drops, and has not coughed since. Discharged cured twelve days after commencement of treatment.

CASE II.—C. S——, three and a half years of age. Has had pertussis six days; has violent attacks at night, also had epistaxis twice. Treatment commenced with two drops three times a day. After three days I increased it one drop, giving three drops three times a day. On the fifth day of treatment child coughed once in twelve hours; cough ceased entirely on the ninth day of treatment.

CASE III.—V. S——, aged fourteen months; in same family as Case II. Began to cough a few days after the above case, probably through infection. At the time of commencement of treatment it had fifteen paroxysms in twelve hours. On the fourth day of treatment, after receiving in all only eight drops, the child coughed but three times in twenty-four hours—once during the day, twice during the night, and each time mildly. The child was discharged, cured, on the sixteenth day after administering bromoform.

CASE IV.—F. E——, aged eight months. Has coughed twelve days; has just recovered from an attack of rötheln (German measles). At the beginning of treatment it had fourteen attacks of coughing in six hours; had six attacks of vomiting in two days. Treatment commenced with two drops three times a day. After the third day I began with three drops three times a day. Cough entirely ceased on eighth day of treatment.

CASE V.—A. S——, aged three years and four months. Cough commenced about two weeks before I saw him. Now has fifteen attacks in twelve hours, also has epistaxis. Considerable vomiting; bowels good, appetite poor, sleep disturbed. Child is considerably emaciated since beginning of cough. Treatment commenced with two drops four times a day, before eating and before retiring at night. Vomiting stopped on the third day of treatment, after the child had received in all fourteen drops of bromoform. Continued treatment for fifteen days, and discharged child, cured, on the sixteenth day.

In this case I lessened the quantity of bromoform, giving but two drops morning and evening the last six days.

CASE VI.—B. E——, aged two and a half years. Has had cough six days, contracted from its younger sister. Began with four to five mild attacks of cough. At beginning of treatment the child had seven violent spells in eleven hours. Treatment commenced with two drops three times a day, and continued until the fourth day; the cough almost ceased on the fifth day of treatment. I stopped treatment owing to complications of morbilli and bronchitis, which at time of writing I am still attending.

CASE VII.—D. S——, aged fourteen months. Had had cough for three weeks when I first saw him. He coughed six times in one hour, and had not slept in six or seven nights owing to continued cough. This child had been under treatment for about ten days before I saw it, had received one-half gramme of chloral for the insomnia, and had also received inhalations of ether, which merely lessened the severity of each attack. The treatment commenced with two drops three times a day, and con-

tinued so until the third day. I then increased the dose to three drops three times a day for seven days, after which the patient coughed but twice in twenty-four hours, both times at night and very mildly. I stopped all medication but bromoform, and after the second night of treatment this child slept six hours continuously; it was then nursed, coughed and vomited slightly (probably from lying on its stomach) and fell asleep, continuing so for two hours longer without bromoform. The treatment was continued for twenty days, after which the child was discharged cured.

Case VIII.—C. K——, two years of age. Had had cough nine days; had seventeen attacks in eight hours. Treatment commenced with two drops three times a day, and was continued for eleven days. I again saw the child on the eighteenth day. It had not coughed in six days, nor had it received bromoform during that time. Child was discharged cured.

Case IX.—W. S——, aged six months. Had coughed for eleven days. At the beginning of treatment it had fourteen attacks in twelve hours. Treatment commenced with two drops twice a day for three days, after which I gave the same dose three times a day I saw this child every second day. By the tenth day it had improved, was sleeping well, and had a good appetite (it was a bottle baby and was fed with barley-water). Child was last seen on nineteenth day and discharged cured. I again saw this child ten days later and found it in perfect health.

Case X.—W. R——, aged twenty-two months. Has coughed between three and four weeks. The mother does not exactly remember when it first began. It had twelve attacks in ten hours. Appetite poor; child is emaciated; it had contracted the cough from a child in the same house. Commenced treatment with two drops three times a day. I increased it on the third day, giving three drops three times a day. This child took in all fifty drops and has not coughed since the treatment was stopped, twelve days ago.

Case XI.—K. P——, three years of age. Had had cough about fourteen days when I first saw her. On the first day of treatment she coughed eighteen times in six hours; had always been well previously; is a very robust and a well-developed child. Treatment commenced with three drops three times a day. I continued and watched carefully until the fifth day, when my patient coughed four times in six hours. I then gave two drops three times a day for eighteen days, and discharged the patient cured on the nineteenth day after commencement of treatment.

Case XII.—M. S——, six years of age. Had had a cough about a month at the time I first saw her. She had eight attacks in six hours, also had epistaxis four or five times since the beginning of the cough. Treatment commenced with three drops three times a day. I increased the dose after the fourth day, and gave four drops four times a day for twelve days. Epistaxis and vomiting were stopped after the third day of treatment. The child was cured after eighteen days of treatment.

Case XIII.—B. S——, aged three years and two months; a brother of Case XII. Contracted pertussis about a week after the above case, through infection probably, and continued until the fifteenth day, after which I saw him. Treatment commenced by giving two drops three times a day. This child seemed better until the fifth day of treatment, when he contracted a violent attack of gastro-enteritis catarrhalis and died.

Case XIV.—K. G——, aged eleven and a half months. Had had cough a little over two weeks. When I first saw the child it was having fifteen attacks in nine hours, and had also had epistaxis once. Expectoration very glairy and tinged with blood. Commenced treatment with two drops three times a day, which had no effect until I increased the dose to three drops four times a day. On the sixth day of treatment I noticed a slight improvement, and on the ninth day of treatment the child coughed but four times in twenty-four hours. On the eleventh day of treatment child had not coughed once in twenty-four hours; the appetite had improved, and it slept well. On the fifteenth day of treatment I discontinued the bromoform. I saw the child on the twenty-second day, found it had not coughed in one week, and discharged it cured.

Case XV.—Mary K——, aged thirteen months. Had had cough ten days when I first saw her. On the first day of treatment the child had eighteen attacks of cough in twelve hours. Commenced treatment with two drops three times a day. I continued it five days, the mother then reported that the child had coughed but three times since the day before, or for about eighteen hours. I discontinued treatment on the sixth day, owing to an attack of enteritis following a very hot day, and after giving the child some tannate of quinine for two days, the enteritis subsided. I again administered two drops three times a day, as before this complication, and although I had stopped the bromoform for two days, the cough was not much worse. I continued treatment for twenty-five days, and discharged the child cured.

Case XVI.—A. E——, aged four and a half years. Had had a cough for five weeks when I saw him. He also had pertussis three years ago, and at that time it lasted about sixteen weeks. He still has a hernia dating from the last attack. Was infected the second time from a neighbor's child; the cough has now existed eleven days. He now coughs seventeen times in eight hours. Vomiting has occurred twice in twenty-seven hours. His general condition is poor; he is anæmic, emaciated, but has no fever. Commenced treatment with two drops four times a day. He slept almost a whole night after the fourth dose, or after having taken eight drops; after the eighth dose, or after the sixteenth drop of bromoform, the child slept soundly during the entire night. I continued treatment until the eighteenth day, when I stopped the bromoform for one week, as the child was very weak. On the twenty-fifth day I put the child on tinct. ferri acet. æth., giving twenty drops three times a day for its anæmia. I have watched this case for two weeks, and have seen no return of the cough.

The above cases will answer to illustrate the different conditions of children attended; patients of all kinds were taken at random, although most cases were seen in the Children's Department of the German Poliklinik; several cases were also seen in the New York Polyclinic.

Most cases that were treated lived in tenements, in badly ventilated apartments, and were, as a rule, poorly nourished subjects, as are usually most dispensary patients. Several cases with the best hygienic surroundings possible, with excellent nursing, the best of food, and strict sanitary regulations were also attended, and I could notice no more benefit than I did in the ordinary class living in tenements. I do not pretend to say, however, that, given the best hygienic surroundings, the best of care, proper dieting, etc., such cases might not, in the long run, be much easier treated, although in my present observation, covering in all fifty-one cases, I noticed no shortening of the disease where better food and air were added.

In all my cases I made it a rule to urge the mothers or the nurses to count the number of attacks of coughing in a given time, say six, or usually twelve hours, as only by knowing exactly how many times a child coughed could the treatment be regulated. I also had the number of severe and the number of mild attacks counted.

In giving bromoform after eating, I refer, in cases of infants, to giving it after nursing; in my cases it made no particular difference whether it was given shortly after feeding or an hour after feeding.

In several cases I gave bromoform before meals, and have noticed no bad effects from the same, although giving it after feeding was preferable.

Baginsky,[1] after going into detail about the etiology of tussis convulsiva, sums up by saying that it is an infectious catarrh, caused probably by a micro-organism, which has not as yet been found. There is no question, however,

[1] Lehrbuch der Kinderkrankheiten.

as to the infectious nature of whooping-cough, and children all through the treatment should be isolated from healthy ones as thoroughly as possible. I have in all used bromoform in fifty-one cases, and still have several under observation; and there is no question but that it is the best known remedy when properly applied. Owing to its discoloration and extreme volatility, I have administered it from dark bottles, or bottles protected from the light, and very well stoppered. If the bromoform turns brown, then it contains free bromine and should not be administered.

The doses required were the following: For children under and up to one year of age, two to three drops three times a day; children from two to four years of age, three to four drops three or four times a day, depending on the severity of the case; children until eight years of age, four to six drops three or four times a day.

The doses were usually increased on the third day, sometimes after the fourth day of treatment, and in very severe cases on the second day of treatment, by gradually adding one drop to the usual dose. The quantity ordinarily required for a cure was from ten to fifteen grammes, although sometimes five grammes was enough; in severer cases twenty grammes, and even more, was required. Owing to its extreme volatility, I could not in most cases exactly determine just how much bromoform had been used. The time required for a cure was variable; in some cases ten days of treatment was enough to effect a cure, others required almost four weeks. About seventy-five per cent. could be discharged cured between two and three weeks after steady treatment, where no other complications existed.

Bromoform should be given in a small teaspoonful of water. Owing to its weight it sinks to the bottom of the spoon, and great care must therefore be taken to see that the child swallows the bromoform, and that it does not remain in the spoon. I did not experience any difficulty in giving it to children, as bromoform has a pleasant taste and was very readily taken by such patients.

40 Rivington Street.

CONTINUED FEVERS IN MALARIAL DISTRICTS.

By OSCAR McMULLAN, A.B., M.D.,

Elizabeth City, N. C.

The burden of this paper will be to record those observations in reference to continued fevers in malarial districts as have come to the writer with such uniform invariableness during the last decade as to have forced themselves upon his mind as facts in medical history. The points to be mentioned and discussed are:

1. Enteric fever runs a milder, though not shorter, course in paludal than in mountainous and unmiasmatic sections, and the probable reason for this fact.

2. The continued fevers observed in malarial regions are bona fide enteric, and not malarial, or so-called typho-malarial.

3. As a consequence of the truth of the second proposition the treatment by quinine, or its congeners, is not only futile but absolutely harmful.

4. The treatment which, in the writer's hands, has given the most satisfactory results.

There can be no doubt, upon a careful perusal of the history of abdominal fever for the last half of the century, as recorded in our classic texts, with parallel readings of recent publications on this subject, that in many sections of the country there has been a gradual decadence in the virulence of this disease and a less frequent observation of its malignant forms. In the language of Peter, "The excessive tympany, the baked tongue, the fuliginous nostril, which made up the usual history of these cases in the time of Chomal and Louis, have almost disappeared with the delirium and the incessant jactitation."

Dabney, in a paper upon the atypical forms of typhoid fever, reaches the conclusion that, at least in many sections of this country, the symptoms which at a former time were thought to be characteristic of this disease and almost invariably observed are now much less frequently present. Especially and in a marked degree has this been found to be true in those regions where the plasmodium malariæ of Laveran is present and bears the power to rule.

Here, in these paludal sections, in the experience of this author, supported by the consensus of testimony of many of the most successful and observant practitioners in his vicinage with whom he has consulted on this point, those conditions and symptoms which we, taught by our texts, naturally look for in typhoid fever, are, as a rule, conspicuous by their absence.

The expected tympany is most always mild when present, and frequently is entirely absent throughout the entire duration of the fever. Iliac tenderness is often elicited only by deep and prolonged pressure, while epistaxis is the exception and not the rule. Constipation generally obtains instead of diarrhœa, and when the latter is present it is mild and quickly amenable to simple treatment. The lenticular and rose-colored papillæ are not usually found, or are but slightly marked, and the hyperthermic line is rarely excessive in its diurnal elevations. In short, all of the classic symptoms of enteric fever are so toned down and illy defined that, but for the sequelæ, the temperature history, and exclusion, the diagnosis would forever remain unsettled.

While other courses—improved methods of treatment, changes in the manner of living, advance in civilization, etc.—may have been mediate and ancillary, the general and essential cause for this decline in the virulence of abdominal fever lies, in the opinion of the writer, in the wider prevalence of miasmatic infection, and certainly this seems to be the case in those regions recognized as paludal in the full meaning of this term. It accords with our experience and observation that when the microbe of Laveran is rampant in the land the bacillus of Eberth is in abeyance, and just in proportion as the community is exempt from the former will it be preyed upon by the latter; until we are led to believe that to be infected with the malarial miasm renders the individual inhospitable to the typhoid germ, and to have been subject to attacks of paludism is a partial vaccination, as it were, against enteric fever, and renders the person less liable to contract the latter disease. Should this fever be contracted all the dreaded symptoms which usually attend upon its onset would be mitigated, as a rule, and the infected person would stand a better chance of a mild attack and ultimate recovery than if, all his life, he had made his home upon the highest and bluest and most salubrious hill of "Old Virginia."

From the meagre study of this subject by the profession the explanation of the preceding observation, of course, as yet remains problematical, but to the writer's mind it seems quite probable that, in a system which has been from year to year inured to pyrogenic bacteria, accustomed to free itself from the noxious products of tissue break-down and microbic ptomaines, and habituated by repeated attacks of infective fever to resist its disastrous and potent exacerbations, with every composite cell of blood and muscle and nerve trained as veterans—here, in such a system, will be found conditions inimical to the full development and ravages of any kindred germ.

It is a well-observed and frequently recorded fact that an individual suffering from one zymotic affection is not liable to furnish a suitable habitat for another, and from these observed facts Hunter formulated the axiom: "Two specific constitutional diseases cannot exist in the same person." And while we do not accept this axiom as embodying a universal truth, still we believe there underlies it a great substratum of scientific fact. It is true that Dr. James Shaw, of Glasgow, observed, which is quite rare, a case of typhoid fever in a well-marked

tuberculous subject, yet the tuberculous advance was stayed by the onset of the typhoid symptoms, and thus Hunter's axiom was not refuted, but only modified to this extent, viz.: Two specific constitutional diseases cannot run their course *contemporaneously* in the same subject; and in the case of Dr. Shaw, narrated above, the enteric poison for one month suspended the action of the bacillus of Koch.

It is well to state in this connection, as bearing collaterally upon this point, that, so far as our observation and inquiry among our *confrères* extend, infectious fevers other than typhoid are rarer and milder during epidemics of paludal fever than at other times. Especially does this hold true in reference to diphtheria; it not having been the author's fortune to meet with a single case of this dreaded scourge during a quite active practice of over ten years, while there has been recorded in other and unmiasmatic sections frequent and almost decimative epidemics. Diphtheria in our climate is indeed a *rara avis*, when the physician well acquainted with its typical history is called upon to make the diagnosis.

In the second place, we believe the hybrid term, typho-malarial or malarial, as designating the fevers under discussion, is without warrant, and, as embodying a false pathology, is pernicious, since leading to an incorrect, futile, and harmful line of treatment. That the plasmodium malariæ may exist, possibly, in the same subject with the bacillus of Eberth we do not deny, since such has been proved recently through the microscopic examinations of Kingoun and others; but in such a case, and we believe the combination to be quite rare, the plasmodium is held in abeyance during the activity of the bacillus of enteric fever, perhaps again to assert itself in exacerbations of fever after the subsidence of the typhoid microbe, thus vindicating the truth of the axiom: Two specific constitutional diseases cannot run their course *contemporaneously* in the same person.

And while the presence of the two microbes at the same time in the same individual may be possible, still this fact does not give the reason or the necessity for the hybrid typho-malarial with any stronger force than in the case of many other affections into which malaria is interjected as a modifying and disturbing element.

That the "continued fevers in malarial districts" are true typhoid we believe, and for the following reasons:

1. The hyperthermic line marks that evening rise and morning fall which is observed in typhoid fever and is considered characteristic of it.

2. The duration of the pyrexia is what we naturally expect it to be in abdominal fever—lasting from fifteen to twenty-eight days.

3. It comes as an epidemic and at a time when intermittent and remittent fevers are remarkably absent. Many members of the same family are frequently consentaneously or consecutively affected.

4. Sometimes in a given epidemic there are observed cases with well-marked typical typhoid symptoms.

5. The sequelæ and accidents of enteric fever are frequently observed. The mildest cases are sometimes complicated by intestinal hemorrhage, and in one instance of a mild, almost walking case, we have seen perforation of the enterous ulcer from dietetic imprudence.

6. The effect from the exhibition of antimalarial treatment, as regards amelioration of symptoms or curtailment of the fever, is absolutely nil.

From these and other considerations we are convinced that the continued fevers lasting from two to four weeks in miasmatic regions are, as a rule, almost without exception, true enteric and not malarial, or so-called typho-malarial.

The obtaining among the profession of incorrect pathological ideas in this respect has led to the adoption on the part of many of nocent methods of treatment; and here comes the point and force of the whole discussion. We are willing to admit that, when called to a case of non-inflammatory and continued fever in paludal districts, it is impossible for some days, and without diagnostic treatment, to say positively what form of fever it is with which we have to deal—whether malarial or otherwise.

For these reasons, when called to a case of the above-described fever, before the history of the case has declared the nature of the pathogenic agent, we treat the pyrexia upon the assumption that it is of paludal origin. Give a dose of calomel to free the *prima via* from fecal matter and pythogenic germs, if perchance they be present, and to arouse to healthy action the emunctory apparatus. Then comes the crucial and diagnostic antiperiodic doses of some one of the salts of quinia for two or three days. If the plasmodia be present, in this agent we have the specific treatment, which, in the vast majority of cases, never fails to eliminate the wily germ.

If after the diagnostic and malaria-eliminative doses of quinine have been taken the fever still continue, the indications for this line of treatment have been fulfilled, and the further prosecution of it will result in harm to the patient, and frequently, we believe, will lead to his death.

The disposition of some medical men in malarial districts to give quinine for everything, first, last, and all the time, *coup ae coup*, whatever the diagnosis of the case under treatment may be, under the fallacious impression that, being in a miasmatic climate, the patient must of necessity, with his other troubles, "have a good deal of malaria in his system too," is fraught with the power of an endless harm to the fever-tortured and pain-racked subject. And right here we desire to raise our voice against the indiscriminate prescribing of this beneficent, but, if indiscreetly used, harmful drug. If we have suspicion, in any given case, that plasmodia be present, eliminate at once the plasmodia and the suspicion by the exhibition of a few judicious doses of the cinchona alkaloids, and then let this line of treatment rest; for experience shows that, at least for seven days, your patient will enjoy immunity from the ubiquitous and malevolent pest of Laveran.

The treatment by quinine of these continued fevers, under the fallacious impression that the primal cause is, in great part, the malarial germ, is without a sound basis either in the theoretical consideration of the subject or in observant clinical experience.

Quinine undoubtedly is a boon to the human race, nor would we pluck one leaf from its justly merited chaplet of praise; but it must never cease to be remembered that instrumentalities that are potent for good, if injudiciously used are equally powerful for harm; and this agent, we feel well assured, has been much and sadly abused, especially in the class of fevers under discussion. Quinine is not a suitable agent with which to combat the hyperpyrexia of long-continued fevers of any nature, and certainly this is true in those cases of fever where there is not only a great breakdown of the body tissues and an overloading of the body fluids with the *débris* of disintegrated albuminoids, but an added intoxication from the specific ptomaïne of the pythogenic agent as well.

Quinine in large doses, or even in lesser doses long continued, impairs the digestive power by direct irritation of the gastric mucous membrane, as well as by its mediate effect through the nervous system. It not only destroys the poor remnant of appetite which the patient may have, but renders the organ incapable of performing its digestive function and of retaining those medicaments which may be deemed essential. Given from day to day in 15, 20, and 30 grain daily amounts, as is frequently done in these fevers, it produces disturbances of hearing and severe headache, and by its constant irritation of the nervous system, encephalic and spinal, raises the already erethitic condition of these structures oftentimes into incontrollable jactitation and wild delirium. Jaccoud emphasizes the danger of the employment of this agent in typhoid fever, pointing out that among the different forms of delirium which may be observed in this fever there is one that it is most important to recognize and avoid, and

that is the therapeutic delirium frequently produced by this very drug. Continued for a long time in large daily amounts, quinine will bring about a positive dissolution of the red blood-corpuscle, a liberation of its pigment, and induce thereby a hematogenous jaundice—thus still further taxing the overburdened excretory organs. As ordinarily given—the sulphate—it is difficult of solution, and in passing from the system through the kidney in a state of unwilling solvability it irritates the delicate endothelium of the tubules into congestion, and possibly may light up a true nephritis, interfering in a disastrous degree with the kidneys secernant action at a time when the blood is surcharged with effete and toxical material and is groaning to be depurated.

What, then, should be the treatment of "continued fevers in malarial districts?" As in other self limited diseases for which we have no specific power of control that method of therapeusis is best which is simplest in its nature and is least perturbative to the sick individual. Many of these cases require no active medication, and with suitable diet and hygiene will progress to a fortunate conclusion.

When the temperature curve is only gently elevated in the evening from two to three degrees, as is frequently the case; when the mind remains elastic and clear, the bowels regular and not tympanitic, and the secretions and excretions are fairly well preserved, no medication is indicated, save, perhaps, a well-diluted mineral acid as a grateful draught to the stomach, an auxiliary to digestion, and a placeboic balm to the mind both of patient and friend. But when the symptoms become more distinctly typhoidal in type—when the fever mounts higher, the tongue becomes drier, the bowels somewhat tender and resonant, and the urine scanty and high-colored—then there are, in my opinion, indications to be met by suitable prescription of medicine. In the light of such objective symptoms, what, manifestly, from our knowledge of this fever, are the organic internal changes to be regulated and possibly hindered?

The microbe of Eberth has found a congenial home in the intestinal canal, and as a result of its rapid proliferation there is set up a dothinenteritis, and upon this inflamed, ulcerous, and absorptive region is deposited the excretory poison, the ptomaïne peculiar to this bacillus. Into the blood it goes with its fever-producing power and commits upon cell of blood and muscle and nerve a more or less extensive destruction.

The albuminoid tissue molecule by this pyrogenic agent is disrupted, and from such decomposition there are formed toxines, from which, if the system be not freed from hour to hour, there speedily results not only an accumulation of the specific poison of the fever, but an auto-intoxication as well.

We know of no means of destroying the germ upon its first lodgement in the intestinal tract, and thus prevent the sequential ulceration and absorption. Some have supposed this could be effected by antisepsis of this canal, working both *per orem* as well as with large enemata *per anum;* but the clinical outcome of such methods of treatment does not show that the ulcerative or absorptive evils have been avoided thereby.

If, then, these conditions of specific and auto-intoxication cannot be prevented, how can they best be limited in their production, how most speedily and effectively eliminated, and their effects upon the system best overcome?

The kidneys are the great depurators, and it is of primal importance that their functional integrity be preserved; for when they cease to any great extent to perform their important work the end is not far removed.

The remedy which we have to suggest, and which in our hands has proved itself to be of inestimable value, is no new one.

The oil of turpentine, first introduced to the profession in the treatment of this fever many years ago by Dr. George Wood, and recently again brought forward with insistence by Professor H. C. Wood, fills more of the indications of treatment in such cases than any other remedy with which we are acquainted. In small doses, begun when the symptoms of faulty excretion and intoxication are first evident, and continued from day to day, the oil of turpentine is a faithful regulator and restorer of excretory power.

As an antiseptic it occupies no mean place in the gradation of this class of remedies, and by this power, in its local effects upon the glands of Brunner and the patches of Peyer, it limits bacillary increase and persuades to the healing process the ulcerated gland. By this action it helps toward the mitigation of the attendant diarrhœa, and, by its hæmostatic power, tends to the prevention of intestinal hemorrhage. It acts mildly and soothingly upon the usually accompanying bronchial irritation, and in the tympany which may arise it is the treatment, in some form, recognized by all. It has a stimulative and tonic effect upon the cardiac muscular fibre, and upon the kidney, judiciously administered, it produces the happiest results.

The caution to be observed is not to give in too large doses, but to obtain just that mild and equable degree of stimulation as shall be sufficient to overcome the torpidity of action which always, to some extent, obtains in this fever. If given to the degree of producing congestion and strangury all good results will be lost and great harm will inevitably ensue. The dose for an adult which I generally prescribe is from five to eight minims in emulsion, to be taken every four hours. Thus:

℞. Olei terebinthinæ pur..... ʒ iij.
Olei gaultheriæ..... gtt. xv.
Pulv. acaciæ..... ʒ iij.
Sacch. alba..... ʒ ij.
Aquæ aromat.....q. s. ad ʒ iv.
M. Sig.: Teaspoonful, diluted, every four hours.

This prescription will bear the addition of lactopeptine if the digestion require it, and of bismuth subnitrate should diarrhœa supervene.

Opiates as a rule are detrimental in typhoid fever and should be reserved for times of great emergency, although we are well aware they are recommended by those high in authority—Flint and others—for diarrhœa, insomnia, etc. There is nothing surer in medicine than that opium checks the secretions and excretions, and especially is this true as regards its effect upon the kidney. To give a dose of opium at a time when the blood is loaded with eliminable poison, and the brain is not only irritated but perhaps lashed into a frenzy by its vellicating circulation, and when the depurative kidney is struggling under the excessive burden it is required to carry, is often the last straw which completes the prostration of this patient, but overworked, helper.

The only indications for opium are in the cases of diarrhœa uncontrollable by all other means, and in the accident of intestinal hemorrhage. The nervous manifestations and insomnia, when present, are best overcome by the bromides, hyoscyamus, chloral hydrate guarded, and the ancillary agencies of quietude and cold sponging.

The antipyretic treatment is rarely indicated in these fevers in malarial regions, since the temperature rarely mounts for any length of time above 103° F. If fever-reducing agents should be required, my preference is the sponge-bath or wet pack, as being less perturbative to the patient than the plunge-bath of Brand, with, perhaps, an occasional dose of some one of the lately discovered derivations of coal tar, acetanilide preferred.

As to diet, I am fully convinced that in the reaction from the old starvation theory to the newer dictum of Graves, "feed fevers," the pendulum has swung too far, and great injury frequently is done the fever patient, not only by improper feeding, but by overfeeding. I have heard doctors say, in giving directions as to diet to these patients, "Drink all the milk and soup you can." This advice causes the patient, who is not only thirsty, but anxious to carry out the injunctions of the attendant, frequently to drink down at a draught a tumblerful of

milk every hour or two. In such an event, after a few days, we gradually have an intestine filled with fermenting milk-curds, the blood overloaded with imperfectly metabolized proteids, and the digestive power, for the want of its recuperative rest, destroyed.

Let the quantity of fluid food, milk or otherwise (and it is best to err on the side of meagreness), be accurately designated, the time set for its ingestion positively stated, and the manner of taking it, slowly and in small sips, strenuously insisted upon. In ordinary cases a period of four hours should elapse between each exhibition of nourishment. This gives the stomach time to do its work and to recover its power, by a proper period of rest, before its functional activity is again required. Frequent but small draughts of cold water, acting both as a diuretic and a febrifuge, will add much to the comfort of the patient and contribute to the ultimate success of the treatment.

Alcoholic stimulation in most of these cases is never indicated, and, if at all, only in the latter days of the fever, or perhaps, at the beginning of convalescence. Given early it will result in no benefit, and possibly in much injury.

Many of the facts and conclusions set forth in this paper have been drawn from a recent list of eight cases which have within the last forty days come under my observation and treatment. Four of the cases are convalescent and the condition of the remainder is very satisfactory. As the teachings of these cases are but confirmatory of the propositions enunciated in the beginning, and as the methods of treatment agree with that outlined above in a general way, I will not call upon the patient reader to go with me through the tedium of a separate recitation of the phenomena observed in each case and the methods of treatment followed.

ELIZABETH CITY, N. C., July 26, 1890.

SUPPURATING ENDOTHELIOMA — MYOFIBROMA IN A CONDITION OF NECROBIOSIS — REMARKS ON THE TREATMENT OF THE PEDICLE, ETC.

BY MARY A. DIXON JONES, M.D.,

BROOKLYN, N. Y.

I FIRST saw endothelioma in the ovary in 1885. It was then pronounced to be "alveolar sarcoma." The patient was thirty-five years of age, had been a sufferer for fifteen years, having at times pain so severe that she could neither walk nor stand, and so sharp and lancinating that she frequently screamed with the agony. After the operation[1] her health greatly improved, she was relieved of the severe suffering, and was able to perform her ordinary duties. In February, 1890, she reported herself as doing the household work for a family of four persons.

Since 1885 I have seen a number of cases of endothelioma of the ovary; each one was characterized by pain directly at the seat of trouble and by certain other marked symptoms. The general health in all was so seriously affected, and there were such grave constitutional disturbances, that I many times queried, Is the growth malignant or semi-malignant? I have been the more impressed with this when I have watched its course, its rapid formation, the infinite number of coarse granules, the vast number of globular and polyhedral corpuscles, and how they infiltrate themselves into other tissues, destroying normal structure and changing everything to their own nature. Future investigation may yet prove this growth to be malignant; that in some instances, however, it has marked boundaries, and, in one at least, was capable of enucleation, would rather indicate its benign character.

When endothelioma exists without the complication of diseased tubes, and consequent peritonitis with pseudo-membranous adhesions, the operation for removing the diseased ovaries is attended with comparatively little shock; and after the removal of an endotheliomatous growth patients usually show a greatly improved condition of general health, are relieved of pain, gain flesh, have renewed strength, and are able to attend to their daily labors or pursue their various occupations; and in many instances have had, by the operation, years of health and useful activity added to their lives.[1]

Endothelioma in the ovary is invariably found accompanied with anomalous menstrual bodies, or gyroma, and is frequently an outgrowth from the same, though gyroma exists in many instances where there is not a trace of endothelioma. Both result from inflammation, and both produce inflammation. Endothelioma finally develops into a profuse new formation of red blood-corpuscles, and blood-vessels, mainly of capillary and venous nature, and at last terminating in what is known as hæmatoma of the ovary; while anomalous menstrual bodies, or gyroma, are the result of certain pathological changes in the follicular membrane, the normal remains of menstruation. This membrane is a delicate, ribbon-like formation, structureless, highly refractive, thrown into graceful folds, and buried deep in the ovarian stroma, and has thus been found unchanged in the ovaries of women over seventy years of age. When subject to pathological action, it first becomes inflamed, broadens, the inflammatory corpuscles begin to elongate, gradually changing to fibrous connective tissue, and meanwhile in the membrane is deposited a waxy, colloid basis substance. As the morbid process advances the convolutions increase in number, till, in some instances, large territories of the ovaries are transformed into hard convoluted masses; and with high powers of the microscope the neighboring tissues are found in a process of change to the same formation. Apparently there is no limit to the formation. Such masses are usually found in a state of intense inflammation, or becoming waxy, or changing into endothelioma, or all these three conditions coexisting. In some instances the gyroma forms firm irregular walls inclosing a varying amount of newly formed myxomatous tissue, and this newly formed myxomatous tissue is frequently found in a state of acute or subacute inflammation, and containing many newly formed or forming blood-vessels. Such great and grave pathological changes must necessarily be accompanied by pain, and by more or less constitutional disturbances.

In an article published in the New York *Medical Journal*, May 9 and 17, 1890, I stated that I first recognized anomalous menstrual bodies, or gyroma, in a case I operated on in October, 1888, and presented the specimen to the New York Pathological Society, December 12th of the same year; but I find I marked this growth, and attempted to describe it, in diseased ovaries which I presented to the same society, September, 1887. I then gave the microscopical examination as "cavernous angioma," with "enormous formations of fibrous connective tissue," "structureless membrane changed to fibrous connective tissue and waxy." "Large irregular cysts filled with fibrous connective tissue, and which might be called fibromata."

These were anomalous menstrual bodies, and the patient was a typical illustration of the two diseases, endothelioma and gyroma. She had the usual well-defined symptoms—pain, pallor, emaciation, and hysteria; gave the appearance of one far gone in phthisis, complained of such severe and continued suffering in the pelvis that she again and again begged to have an operation performed for her, and was impatient of any delay. We delayed from time to time, because of her extreme feebleness and the poor prospects of her surviving the operation; and if she did survive, we could not at that time see how the

[1] The uterine appendages were removed June 25, 1885. I was kindly assisted by Professor Gill Wylie and Dr. C. N. D. Jones. Samuel King, M.D., attended to the ether.

[1] Many have also stated, as a result of the operation, that the marital relations were no longer painful or unendurable, but the contrary.

removal of the diseased ovaries would so radically benefit her general condition or restore to health one so seriously affected. Finally, as the patient continued to grow worse, and her symptoms were becoming more and more unfavorable, we decided to perform the operation, in hopes of relieving her, in some respects, at least, and hoping that relief of other and more grave symptoms might follow.

The results following the operation were beyond our expectations. The patient was relieved of pain, gained in flesh and strength, looked well, all appearance of phthisis disappeared, and she was soon able to do the household work and washing for a large family.[1]

Thus the endothelioma and gyroma had affected her whole system, producing serious and profound constitutional disturbances, and I believe her improvement was entirely due to their removal.

In the ovaries of this patient were large cysts filled with fluid; some sections of the ovaries showed that these cysts occupied three-fourths of the space or surface, thus much of the normal ovarian structure was thereby destroyed, while the remaining parts of the ovary, which were really only the rims and interstices around and between the cysts, were in a state of intense acute and subacute oöphoritis, and some portions of this inflamed structure had already degenerated into endotheliomatous and gyromatous formations. The blood-vessels were diseased, the walls of many were in a state of intense inflammation, others were in waxy degeneration. The ova showed profoundly diseased conditions; many were completely filled with inflammatory corpuscles, some were changing to fibrous connective tissue, many were waxy, so they, the ova, so far as any physiological function was concerned, were utterly destroyed. We believe the septic peritonitis developed at the last parturition not only produced the endothelioma and gyroma but also caused this diseased condition of the ova.

We find further in the ovaries of this patient a number of large lakes of ready-formed blood. This condition was necessarily attended with much possible danger, and rendered a delay in the operation extremely hazardous to the life of the patient. One instance is reported of a hæmatoma of the ovary bursting, blood escaping into the peritoneal cavity, causing a severe peritonitis—pulse 140, temperature 104° F.—and only a timely operation saved the patient's life. When a rupture once takes place in these fragile tissues, considering the large blood-vessels that may be opened, we see the great peril in which the patient must necessarily be placed.

The existence of endothelioma in the ovary also produces certain conditions in the surrounding tissue that may give rise to unexpected and serious difficulties in the operation. An engorged pampiniform plexus, or "varicose dilatation of the veins of the broad ligament," is no doubt a frequent result, and an accompaniment of an advanced condition of endothelioma or hæmatoma.[2] In this patient the pampiniform plexus was greatly engorged and the neighboring tissues were tender, and had a tendency to bleed, even the fundus uteri oozed blood at the slightest touch; the broad ligament tore like wet paper, tore even from the cornu of the uterus, and melted under the secured ligature so that the whole broad ligament was unfolded, countless vessels opened, pouring forth their life-current, and in a moment the pelvis was welling up full of blood. These bleeding-points were quickly secured, clots removed, the peritoneal cavity flushed out, and the patient made an excellent recovery, though it was somewhat delayed on account of the continued oozing preventing the abdominal wound from healing readily and causing the consequent formation of much cicatricial tissue; still she was able to leave the hospital in a few weeks, commenced her heavy household labors, and her husband said he had not seen her so well for fifteen years.[1]

Such peculiar conditions of the tissues in the pelvis may explain the serious hemorrhages that in some instances occur, not only unexpected by the surgeons, but apparently without cause. While we do not fully understand the nature of endothelioma, or its probable effects upon the ovaries and surrounding structures, yet we must recognize that it is a serious disease: First, on account of the local suffering; second, the general ill health and indisposition it produces; third, the dangerous condition of angioma or hæmatoma; fourth, the possible hemorrhages, which may be immediately fatal or followed by a fatal peritonitis; fifth, the possibility of its suppurating. Of this last condition I will speak, and it is illustrated by the following remarkable case, and is, I believe, the first instance yet recorded of an endothelioma being found in a state of suppuration. This patient first called to see me in company with her husband, on August 11, 1889; she was thirty-three years of age, married nine years, one child eight years of age; she was very anæmic, somewhat emaciated, lips white, mouth dry, great thirst, pulse 115, temperature 102½° F.; complained of constant and severe distress on each side of the pelvis, sharp cutting pains in the bladder, could not lie on the right side or turn from one side to another without great pain, hurt her to walk, and when she attempted it she reeled and tottered from absolute weakness. She often said: "I feel so bad, so bad, I cannot live as I am."[2]

Upon examination I found a myoma occupying the entire structure of the uterus, and the uterus, thus enlarged, was pushed down in the lower part of the pelvis, so that the os protruded beyond the vulva, the whole mass thus making pressure upon the bladder and rectum. I diagnosed further that the patient had endothelioma of the ovaries and pyosalpingitis of the tubes. The high temperature was supposed to result from the local peritonitis excited by the latter. Here I wish to emphasize, as I have elsewhere[3] suggested from studying the histology of these morbid conditions, that it was the disease of the uterine appendages that caused the growth of the tumor. Some German writers maintain[4] that a fibroid tumor or a myoma develops in consequence of sterility, or the inactivity of the sexual organs; others, as Winkel and Röhrig, say the sterility is in consequence of the tumor. Neither of these propositions can be sustained by facts; but that disease of the uterine appendages causes sterility is self-evident, and also that these diseases do so disturb the nutrition of the uterus as in many instances to cause the development of myoma is almost equally self-evident;

[1] After a patient is thus relieved in consequence of an operation and is in comparative good health, we naturally say, "What a pity her ovaries are gone." So it is, the saddest pity. We may even demand why this operation was performed, and the woman thus prevented from having more children. We forget that her former conditions were such that it was not a question of children or ovaries, but of saving life and trying against hope to give the sick woman a degree of health and comfort. We forget, too, that the disease that produces such distress produces also a profound sterility. A gangrenous finger is removed, and life is thereby saved; still we may well regret the loss of the finger. Dr. H. Byford, of Chicago, says: "The cry that we are depriving woman of her God-given organs is nonsensical. I have not yet learned that a woman is unsexed by the change of life, whether naturally or artificially; and after the sexual system of a woman is modified by the change of life, or removal of the ovaries, she is in as good or better condition than before to live out her days" (Chicago Obstetrical Society).

[2] Dr. H. C. Coe well expresses the general principle when he says: "The same cause may lead to both the ovarian disease and the dilatation of the veins" (American Journal of Obstetrics, p. 511, May, 1889). Dr. R. Nilsen says: "The destruction of veins will disappear, together with the symptoms, upon the removal of the diseased uterine appendages" (Ibid., p. 518, May, 1889).

[1] The doctors watched over this patient and cared for her with unceasing vigilance. Probably for this service and for saving the patient's life, she, the patient, may one day be persuaded to bring suit against the doctors for heavy damages, as one patient who was relieved by a similar operation in the Woman's Hospital of Brooklyn, who had equal care and attention from the doctors and the nurses, sued the doctors for many thousand dollars; though the modest wish of this patient, as she herself expressed it, was "to get a hundred dollars to buy a store."

[2] This patient was advised to consult me by a gentleman whose wife was a patient in the Woman's Hospital of Brooklyn in 1887. In her case the ovary was enlarged by an endothelioma and was bound in a mass of pseudo-membranes to the pelvic floor. Her conditions were further seriously complicated by a severe form of interstitial pyosalpingitis. The uterine appendages were removed; the patient made a rapid recovery, and is now in the enjoyment of excellent health.

[3] New York Medical Journal, August 25 and September 1, 1888.

[4] Handbuch der Frauenkrankheiten, vol. ii.

and as corroborating the same point is the fact that the timely removal of the uterine appendages will not only stop the growth of the myoma, but will in many instances cause its entire disappearance.

Soon after the birth of the child this patient had salpingitis, accompanied by more or less oöphoritis. If the diseased uterine appendages had at that time been removed there would have been no tumor, and the long years of suffering might have been avoided. Still, if this operation had then been performed we would doubtless have heard again about "mutilating women" and "rendering them sterile;" yet we notice that leaving the diseased uterine appendages did not enable her to have children, did not make her a more perfect woman, or render her less mutilated; but did make her a miserable invalid, did incapacitate her for every useful employment, and did, in time, produce conditions that were dangerous, and finally fatal.

At the next menstruation this patient hemorrhaged seventeen days, and during the whole period suffered with extreme pain and prostration, and became more and more exhausted. The pulse and temperature had previously a little improved, still in essential respects the patient was steadily losing ground, and in every way the prognosis of her case was most unfavorable. We did not think she had strength, or that it would be possible for her to pass safely through another period; it was equally evident she could not live without an operation; with one there might be a small chance. Still I hesitated to admit so hopeless a case into the hospital, submitted the question to the trustees, who considered the matter, and decided that as the object of the hospital was to save life, and help suffering women, therefore they could see no reason why this sick woman should not be admitted, and an effort made to save her. She entered September 5, 1889; temperature, 101° F., pulse, over 100; had every care, rest, quiet, good nourishment, and constitutional treatment; still her temperature continued to range from 99½° to 101½° F. in the morning, and 100° to 102° F. in the evening. This regular rise and fall of temperature showed some septic or hectic condition which was still attributed by the attending physicians to the local peritonitis. Dr. H. C. Coe and Professor William Polk both very kindly examined the patient, and both were of the opinion that if the tumor were allowed to remain it would be a serious peril to the patient. Dr. Coe wrote me, October 18th: "The uterine fibroid is firmly impacted in the pelvic cavity, so as to cause serious pressure upon the neck of the bladder. If the tumor continues to grow and to occupy its present position, from which it seems impossible to dislodge it, the patient will certainly be placed in great peril from retention of urine and its consequences, added to the serious danger of continued hemorrhage. I do not see how any operation except complete removal of the mass can benefit her, and I regard such an operation as justifiable."
